1. The postmortem findings of 23 patients receiving intravenous gelatin therapy who expired as a result of medical and neoplastic disease or from complications of therapeutic surgical measures, are reported as demonstrating the etiologic rôle of gelatin in the pathogenesis of renal hydropic changes morphologically similar to those produced by the intravenous injection of sucrose.

2. The morphology of the renal lesion produced by gelatin is described and compared with that of sucrose nephrosis.

3. Gelatin nephrosis is shown to be a reversible change occurring within half an hour after the intravenous injection of gelatin and disappearing within 120 hours following the last injection.

4. Studies of the effect of the renal lesion on renal function are reported as inconclusive but 2 suggestive cases are discussed, one showing diuresis and the other oliguria following the intravenous administration of gelatin. Caution is suggested in the use of this substance in patients exhibiting previous renal impairment.

5. Attention is directed to the possible rôle of gelatin in promoting circulatory disturbances and 3 cases are reported as suggesting gelatin as a potential precipitating factor in coronary occlusion and vascular thrombosis in the presence of circulatory disturbances and vascular disease.

found to have a duodenal ulcer from which gas escaped into the tissues. Three cases of endometrios were reviewed 2 of the lesions were in the appendix and the other in the ileum.

SUMMARY AND CONCLUSIONS

A general survey of the tumors arising in the gastrointestinal tracts of members of the armed forces between 18 and 38 years of age has been made. The results of this survey as to relative frequency and anatomic distribution is largely summarized in the accompanying tables and charts. These overall figures follow those of previous reports. The most salient features brought out are these:

1. Carcinomas of the large intestine and rectum constituted over three-fourths of all of the carcinomas of the gastrointestinal tract.

2. Carcinomas were most frequent in the older age group but mortality was relatively higher in the younger age group.

3. Polypoid lesions of the intestinal tract were observed most commonly in the rectum. No recurrences resulted after local excision.

4. Carcinoid occurred most frequently in the appendix, but those in the rectum were commonly confused with carcinomas.

5. The most frequent tumor of the lymphoma group was the benign lymphoid polyp. These tumors were commonly found in the rectum and local excision was followed by no subsequent evidences of recurrence or transformation into the malignant type.

were 5 instances of multiple tumors. The granuloma of Hodgkin's disease was in the small intestine and the ileocecal lesion was among the 20 cases of reticulum cell sarcoma and lymphosarcoma, and another in the case of leucemia. Follow up records in the case of Hodgkin's disease were incomplete. Five of the lymphoid tumors were seen in individuals under 21 years of age, 14 in those between 21 and 30 and 3 in those between 31 and 38.

MISCELLANEOUS

Among the less common tumors in this survey there were 7 malignant melanomas, 6 of them metastatic in origin, only 1 was believed to have arisen in the ileum. Four neurofibromas were located in the appendix and were discovered at operation for what appeared clinically to be acute appendicitis. One ganglioneuroma of the cecum occurred. It measured 6 centimeters in diameter. In the instance of hemangioma recorded the lesions were multiple and were located in the ileum. One unusual gastric tumor was a hemangiopericytoma and undifferentiated sarcoma of the stomach and undifferentiated sarcoma of the jejunum. Lipoma, myxoma, lymphangioma, teratoid and other tumors, sometimes reported to occur in the gastrointestinal tract, were not observed in this series. The reason for this probably lies in the screening system previously described.

There were 8 cysts of the gastrointestinal tract, 4 related to the esophagus and 4 to the small intestine. Three of those in the esophagus were lined by respiratory epithelium and 1 was a parasitic cyst due to ankylostomiasis. Of the 4 in the small intestine the other 3 were enteric cysts lined by columnar epithelium. One mucocle was seen in the rectum. It was associated with a polyp. Of interest, too, was a case of pneumatoxis cystoides intestinalis for which a segment of ileum was resected. The patient was subsequently

SODIUM PENTOTHAL ANESTHESIA FOR
SELECTED VAGINAL OBSTETRICS

A. LOUIS DIPPET, M.D. FACS, R. J. HELMAN M.D. C. E. WOLTERS, M.D.
H. A. WALL, Jr. M.D. and F. H. HAIRSTON M.D. HOUSTON TEXAS

The use of intravenous sodium pentothal in obstetrics is not new. Several reports having appeared in the literature during the past 10 years (3, 5, 8, 9, 12, 14). Some have employed it as the sole or major anesthetic agent routinely in obstetrics (3, 8, 12) whereas Labrecque reserved it for use in cases of severe upper respiratory infection bronchitis, asthma, tuberculosis, bronchopneumonia, and after ingestion of large meals. Hunt and Grundy employ it in connection with local infiltration for cesarean section withholding the use of pentothal until the abdomen has been entered and the operator is ready to proceed with incision of the uterus and immediate extraction of the fetus. Several (8, 9) contend that it is an unsatisfactory anesthetic agent for obstetric version with extraction on the grounds that the relaxation which it produces is inadequate. Hellman (3) and Kucker (13) do not agree with this contention in view of the fact that 1.5 per cent of Hellman's operative deliveries and 7.3 per cent of Kucker's deliveries involving a viable infant were effected by this method.

Our use of intravenous sodium pentothal as anesthetic for vaginal delivery was instituted during World War II because of the shortage of anesthetics available for routine ward deliveries. It had been immediately preceded by the use of open drip ether which was given by various untrained hospital employees, but this was abandoned after the occurrence of a serious case of vomiting under ether anesthesia followed by aspiration pneumonia which necessitated hospitalization of the patient for almost 3 months. That older members of the staff could not recall ether smaller tragic or near tragic cases is truly remarkable.

From the Division of Obstetrics, Harvard Hospital, and the Department of Obstetrics, Harvard College of Medicine, Boston, Massachusetts.

depression with anesthetic dosage but this is not alarming. Pentothal will effect an elevation of blood pressure particularly systolic but the elevation is not sustained though the immediate systolic rise may amount to as much as 20 millimeters of mercury (8). It leaves the pulse unaffected or somewhat slower. Other pharmacological characteristics have no clinical bearing. Laryngospasm is frequently mentioned as an effect of intravenous sodium pentothal anesthesia but actually appears to be rather uncommon more particularly when its use is preceded by a hypodermic of atropine or of hyoscine.

Intravenous sodium pentothal rapidly traverses the uteroplacental barrier to depress fetal respiratory movements and to retard the initiation of respirations in the newborn. Hellman, Shettles, and Stran (4) found that within 10 or 12 minutes it reaches equal concentrations in fetal and maternal blood. They found that during the first 5 minutes after beginning the anesthetic, little of the drug reached the fetus. Dreisbach and Snyder showed that when the experimental rabbit was given 10 milligrams of pentothal intravenously per kilogram of body weight at term, the fetal respiratory rate was decreased to one-third the initial rate for a period of about 5 minutes, and that after a total dose of 3 to $5\frac{1}{2}$ times the above amount there was relatively little cumulative effect upon the fetus. In this connection it should be pointed out that the above smallest experimental dose is comparable to the average total dose used in our series.

It has been suggested that intravenous sodium pentothal should be avoided as an anesthetic in certain toxemia patients because of the presumed destruction of the drug by the liver and the possibility of added degenerative changes in that organ (11). The frequent moderate elevation in systolic blood pressure might also be used as an argument against its use in connection with the severe hypertensive toxemias of pregnancy. However Rucker (13) seems not to have considered this maternal complication as a serious contraindication to its use. In general, however there seem to be few valid contraindications to its use in obstetrics. It is conceded that pentothal with

its respiratory depressant effect is undesirable in heart disease with decompensation with marked anemia, in the face of dyspnea attributable to pathological processes in the thorax or if there is any reason to think that the respiratory passage is, or may become obstructed. It is ideal that the stomach should be empty in order to eliminate vomiting. Also pentothal is known to increase laryngeal reflexes and vomiting would then tend to increase the incidence of laryngospasm. There are individual idiosyncrasies to pentothal but these are surely uncommon. Hunter has reported a case with cutaneous manifestations in the form of erythema multiforme followed by pustule formation and pyrexia when the anesthetic was later repeated. It goes without saying that the solution should be injected intravenously and not into the extravascular tissues nor into the arterial tree. Lundy (10) records several cases of intra arterial injection of sodium pentothal. All of these patients experienced varying amounts of pain in the injected arms. One of these succumbed to an overdose of pentothal. The induction of anesthesia in this case was prolonged with an excessive amount administered. Death followed the delayed entrance of the overdose of the drug into the general vascular system via the arterial as compared with the intravenous route. Lundy advises the use of an intermittent tourniquet to the affected arm and oxygen inhalation whenever a large amount of the drug is administered intra arterially. Dixon and Lundy (10) have indicated that 10 per cent concentrations of sodium pentothal injected into the perivenous or subcutaneous tissues produce pain and irritative manifestations, sometimes even with sloughing of tissue but Jarman claims that 5 per cent solutions are almost innocuous when injected into these tissues and that it is unusual for these patients to complain of even a sore arm. Lundy (10) says that thrombosis was frequent with 10 per cent solutions but that its incidence has been reduced in proportion to the reduction in concentration of the drug.

Between July 24 1945 and October 1 1946 350 patients from both ward and private services of the Hermann Hospital were delivered of viable pregnancies under intravenous so-

TABLE I.—ANALYSIS OF 350 PATIENTS DELIVERED UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO DEPARTMENTAL AFFILIATION AND RANK OF ANESTHETIST

Professional anesthetist	1	
Totals	350	100.0

Race and economic level, the latter determined from admission status, of each patient in the series will be seen in Table II. The hospital has no accommodations for private colored obstetric patients. The distribution between the races for both ward and private patients is roughly the same as for these services as a whole. Sixteen private physicians delivered patients under intravenous sodium pentothal anesthesia but 9 of these can be considered casually for each accounted for a maximum of only 3 deliveries. This does not mean that the 9 tried and discarded pentothal for short vaginal delivery but that their number of deliveries over the period of time under consideration was correspondingly low. Thirty was the maximum number of deliveries accounted for by any one private physician.

Age of patient is recorded in Table III. Since there was no selection of patients for pentothal anesthesia on the basis of age, the observed age distribution is essentially the same as for the service as a whole. Two patients were less than 15 years old actually each was 14 when delivered.

Mention has already been made of the departmental policy of preferring no analgesia

and local infiltration anesthesia for the handling of premature labor and delivery. There were however 7 premature births in this series. Two of these involved intrapartum fetal death due to premature separation of the normally implanted placenta, each at 30 weeks gestation. The remaining 5 premature deliveries advanced to 34 weeks (1 case) and 35 weeks (4 cases) gestation were effected with dispatch so that the premature infants with birth weights ranging from 4 pounds 6 ounces to 5 pounds 3½ ounces were born without narcosis, required no resuscitation and were all raised. The remaining 343 (98%) gestations produced near term term, and postmature fetuses, i.e. each newborn was at least technically of term size—weighed at least 2500 grams (5½ pounds).

Table V reveals that there was no selection of patients in regard to previous obstetrical experience. Fifty three per cent were multiparas, only 4 being in the grande multipara range. One of the essential primiparas had had 6 previous abortions, 2 had had 2 each and 14 had each previously aborted once. There were 4 young primiparas, i.e. patients delivering a term or near term pregnancy before the sixteenth birthday anniversary. They

were all ward patients, 1 being a Mexican 15 years old and 3 colored one 15 years, and two 14 years of age. Four patients were true elderly primiparas, i.e. were delivered of the first viable pregnancy after the thirty-fifth birthday anniversary. One of these was a 39 year old private white woman and the others colored patients 36 to 39 years of age. Five were elderly essential primiparas or were delivered of the first term or near term pregnancy after age 35 but in each instance the viable pregnancy had been preceded by 1 or more abortions. Four of these were white private patients each of whom had had 1 previous abortion the oldest was 42 years of age. 1 colored elderly essential primipara was 37 years old and had had 2 previous abortions.

The various primary fetal presentations and positions are recorded in Table VI. Manual

or forceps rotation from an occiput transverse or posterior to an anterior was employed 35 times.

In Table VII it will be seen that 110 fetuses (31.3%) were delivered spontaneously under intravenous sodium pentothal anesthesia. This figure is almost identical to that reported by Eastman (3) whereas Rucker (13) reports only 8.3 per cent spontaneous deliveries when a viable infant was involved. LaBrecque reports the highest incidence of spontaneous delivery namely 57 of 80 deliveries (71%), with the use of either sodium pentothal or evipal soluble. In this connection it must not be forgotten that pentothal will efface bearing down efforts in 60 per cent of the patients anesthetized with it whereas evipal does not unfavorably affect this reflex mechanism (9). The low incidence of podalic version and of midforceps delivery in the current series reflects the conservatism of the service. The version and extraction was performed on the patient with transverse presentation of the fetus and prolapse of the umbilical cord. One midforceps delivery was used for delivery of a second twin while the other 2 midforceps deliveries occurred on the private service. Pen-neorraphy for correction of a previously noted

rectocele was performed in connection with 8 private deliveries. One vaginal and 2 cervical tears were known to have occurred with low forceps delivery and all were repaired under pentothal anesthesia. Forceps to the after coming head were applied in 5 instances Mauriceau maneuver being employed in the other 6 breech deliveries.

The accoucheur for each delivery is recorded in Table VIII. Only 2 ward deliveries were not actually effected by the house staff—the version with extraction and a difficult low forceps due to an excessive-sized fetus with erythroblastosis associated with a contracted pelvis.

As previously stated, a 2 per cent solution of pentothal was administered intravenously. The amounts of the drug employed are shown in Table IX. Unfortunately the amount used was not recorded in 100 (28.6%) of the cases. Of the remaining 250 in which the exact amount administered is known only 21 (8.4%) received more than 50 cubic centi-

TABLE IX.—ANALYSIS OF 350 DELIVERIES UNDER INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA ACCORDING TO AMOUNT OF DRUG EMPLOYED IN 2 PER CENT SOLUTION

meters (10 gm.) The largest amount given 135 cubic centimeters (27 gms.) was for the Mexican woman with a contracted pelvis and an excessive-sized erythroblastotic, stillborn (intrapartum death) delivered by prolonged and difficult low forceps extraction. She had received little analgesia. Spontaneous delivery without perineal repair was effected once with only 6 cubic centimeters of solution and a breech extraction of a stillborn premature (intrapartum death) without repair in another instance with 8 cubic centimeters. The average for the series was 39 cubic centimeters (0.78 gm.) In large measure, the amount of anesthesia varied with the amount and recency of administration of analgesia, but such correlations cannot be graphically shown by usual methods. However the various analgesic drugs with time interval between last dosage and moment of birth of the child are recorded in Table X. Of interest are the great variety of drugs and combinations of these used to obtain analgesia. It was rather surprising to discover that 182 patients, 58.7 per cent of those receiving analgesia, received the last dose of the analgesic less than 2 hours before delivery of the infant. Obviously this fact must be remembered when noting the

dosage of anesthesia required. It must also be remembered as a factor in the production of apnea in the newborn infant.

As will be seen in Table XI 14 patients (4.0%) received supplementary anesthesia. In addition to these perineal block was the original anesthetic agent which was abandoned for intravenous sodium pentothal when the patient was declared too unco-operative (2 cases) when an unfavorable fetal position was discovered at vaginal examination (3 cases) and when 1 delivery was unduly prolonged due to fetopelvic disproportion. Actually the supplementary anesthesia given was rarely the result of failure of pentothal anesthesia. For example, one accoucheur was so suspicious of pentothal that he effected delivery (3 cases) under it but completed perineal repair under local infiltration. In 4 cases supplementary anesthesia was used in order to avoid preparation of a second gram of pentothal solution. In another instance the resident experimented with nitrous oxide as an adjuvant to pentothal. In the final analysis, then, intravenous sodium pentothal was seriously or majorly complicated in only 3 instances, an incidence of 0.86 per cent. In the first of these the drug itself cannot be blamed for it was administered into the tissues outside the venous system. Moreover in the other 2 there is reason to suspect that better control of the sodium pentothal anesthetic or of vaginal manipulation might have avoided complications, for in one the patient is said to have been hard to manage under pentothal. In other words, de-

livery was effected or at least attempted without obstetrical anesthesia, while the other vomited after delivery of the child, a time when the original dose frequently wears off. The latter patient swallowed so much air that Wangensteen suction had to be employed 8 hours later.

The case of the patient receiving extravenous injection of sodium pentothal warrants more detailed presentation. She was a 26 year old secundipara with a normal pregnancy at term who was given demerol (100 mgm.) and hyoscine (gr 1/150) both intravenously 2 1/4 hours before delivery and demerol (100 mg) subcutaneously 1 hour before delivery. Anesthesia was attempted with the usual 2 per cent solution of sodium pentothal. After the injection of 30 cubic centimeters with no apparent anesthetic response from the patient, open drip ether was substituted. The intravenous needle had apparently perforated both vein walls with the pentothal injected beneath a fascial plane since blood had initially been drawn back into the syringe and there was no tumefaction in the subcutaneous area. After an episiotomy had been done and the child delivered by low forceps extraction, it was noted that the patient's respirations were mildly depressed. The child was in good condition. The episiotomy was repaired without further administration of an anesthetic. The mother's respiratory depression was apparently from absorption of pentothal but was combatted with coramine. She slept for 3 hours after delivery. Some 14 hours later the patient complained of pain in the right arm and several areas of hyperemia were noted near the site of venipuncture. There was little swelling in this area and the corresponding ulnar pulse was normal. Hot moist applications to the affected area were continued for 3 days when the arm became comfortable and there was apparently no residual effect from this accident. As previously noted, cases of this kind followed by irritative symptoms, even sloughing of tissue, are known to occur with 10 per cent solutions but not with concentrations of pentothal not in excess of 5 per cent.

Complications of pregnancy labor and the puerperium are listed in Tables XII XIII and XIV respectively. It will be noted that

56 per cent of the patients had no complication of pregnancy 49 per cent had none in labor and 85 per cent none in the puerperium. Moreover 105 patients or 30 per cent, had normal pregnancies, labors and puerperia.

Intravenous sodium pentothal anesthesia as noted previously does not affect uterine contractility or contractions. The average estimated blood loss in this series of deliveries was 168.4 cubic centimeters and the distribution of estimated blood loss is recorded in Table XV. In order to ascertain whether estimated blood loss varied with anesthetics other than pentothal 100 consecutive cases were reviewed of patients delivered in the same period of time, under other anesthetics but by the same group of accoucheurs who had used intravenous sodium pentothal anesthesia. No statistical difference could be found in any anesthetic group nor in any group of accoucheurs—rotating internes residents or private physicians. Local caudal spinal saddle block and various inhalation anesthetics and combinations thereof except chloroform were included in this differential study. It seems safe to say therefore that intravenous sodium pentothal anesthesia does not increase blood loss in the placental stage. Neither does it appear to decrease the amount of bleeding in that stage.

It is not easy to evaluate the amount of resuscitation required by a group of newborn infants delivered by a heterogeneous group of physicians and house officers since some employ oxygen vitamin K coramine, or even a

mechanical resuscitator if the newborn child does not cry vigorously and promptly after delivery. However it was found as shown in Table XVI that 270 or 77 per cent of these newborns required no resuscitation whatsoever i.e. cried or at least breathed regularly and promptly after delivery. Forty four or 12.5 per cent required little or only slight resuscitation. In these aspiration of mucus or amniotic fluid was followed by mild cutaneous stimulation in the form of rubbing the back or thumping the toes or fingers. Pure oxygen was administered to 9 of these but in each instance it is stated that resuscitation was of minor importance. That pentothal was responsible for apnea in these is far from proved. Actually in one the drug could not have played a rôle for the child was born before the patient could be completely anesthetized. However in 9 instances the newborn is said to have been mildly narcotized in 2 there was a loop of umbilical cord about the fetal neck in 1 mild cyanosis, in 2 much aspirated amniotic fluid and in the remaining 30 there was no recorded or recognizable reason for the mild initial apnea. Analgesic drugs appear to be involved especially in the light of their frequent administration late in labor. However all the above 314 newborns (89.5%) requiring little or no resuscitation were actually born alive in good condition and survived the immediate neonatal period with a single exception—1 requiring no resuscitation, found dead in its crib 6 hours after delivery believed to have suffocated in which autopsy revealed only adrenal hemorrhage.

There remain 37 infants, 10.5 per cent of the series, in which minor degrees of resuscitation were inadequate. All but 1 of the infant

(a) Was found dead in crib, believed suffocated at age 6 hours.

(b) Lived 1 hour.

(c) Delivered by cesarean 70 minutes before delivery, cord around neck.

(d) Passed much mucous stained amniotic fluid, lived 14 hours.

(e) One of those received no analgesia, admitted directly to delivery room, had aspirated much mucous stained mucus, lived 6 hours.

(f) Breach breaker up, contracted pelvis, forceps to shortening head, legs broken, died 3 hours.

(g) Mild breech extraction, cesarean, one fetus (no Rx. to see), lived hours, no autopsy cervical hemorrhage.

deaths are included in this group. The apparent causes for major degrees of resuscitation or of fetal loss are included in Table XVI. In no case did sodium pentothal appear to play any serious rôle in resuscitation or in survival of the newborn. The most serious effect of pentothal in this series was noted in a second twin delivered by midforceps extrac

STREPTOMYCIN THERAPY IN URINARY TRACT INFECTIONS

EDWIN J PULASKI Major M.C. A.U.S. and WILLIAM H AMSPACHER, Colonel M.C. U.S.A.
Fort Sam Houston Texas

DATA on 465 patients with urinary tract infections in United States Army hospitals receiving streptomycin therapy have been assembled and submitted to critical analysis. The results of this study are presented in this communication.

Urinary tract infections constitute a serious problem in Army hospitals. The reasons for this are manifold.

1 The number of patients with paraplegia in whom ascending urinary infection is a constant threat and a serious complication.

2 Infections in patients with wounds or injuries involving the urinary system including perforations of the bladder, cicatricial deformities of the ureters, and injuries to the genitalia and kidneys. In this group of patients cystotomies and instrumentations have resulted in or were followed by stubborn and unyielding infections.

3 Infections in otherwise healthy individuals due to the usual causes of stasis and obstruction.

4 Infections superimposed upon new growths.

5 The fact that no specific agent has been available hitherto for infections due to *Pseudomonas aeruginosa* and *Streptococcus fecalis*.

6 The inconstant responses, with drug fastness frequently ensuing in many cases of gram-negative bacillary pyuria treated with sulfonamides.

Penicillin is of no value in the treatment of infections due to gram-negative bacilli. Older drugs such as mandelic acid have well known limitations. The need of a potent drug which is effective against bacteria causal of infection in the urinary tract is only too well appreciated.

This project was carried out as a part of the study being made under the direction of the Army Medical Research and Development Board, Office of The Surgeon General.

From the Surgical Research Unit, Brooke General Hospital.

Early reports (7) and our own observations (6) indicated that streptomycin has a potent *in vitro* action on many gram negative as well as gram positive bacteria including the acid fast bacilli. Among these are *Pseudomonas aeruginosa*, and *Streptococcus fecalis* usually refractory to other drugs. We demonstrated (6) that doses of 0.4 gram of streptomycin administered intramuscularly every 4 hours produces levels in excess of 1 milligram (1000 units) of the drug per cubic centimeter of urine and maintains a blood serum level of 16 micrograms (units) per cubic centimeter. These levels are in excess of the amount of antibiotic required to inhibit the growth of 87 per cent of the bacteria usually recovered from infected urine. A preliminary report of the effect of streptomycin therapy in infections of the urinary tract has already been published (5).

RESULTS OF THERAPY

1 *Criteria* The results of treatment with streptomycin have been catalogued according to (1) clinical response, and (2) bacteriological result. The evaluation of clinical response is based on changes in symptoms and fever and the gross and microscopic alterations of the urine. Those patients obtaining complete relief of symptoms and repeated sterile urine cultures are considered 'cured'. Those with remission of symptoms in whom the urine was grossly cleared, but with cultures remaining positive are classed as improved while those with continuing pyuria and no symptomatic relief constitute failures.

In classifying the bacteriological results a "cure" signifies sterile urine cultures for the period of observation (usually 2 weeks after cessation of therapy) while a "failure" denotes a urine culture which continues to show pathogenic bacteria. In some instances sterile urine cultures were obtained within 24 to 72 hours after the institution of therapy, but sub-

tion whose mother had been anesthetized for 16 minutes before this co-twin was born. The newborn was obviously narcotized and required moderate resuscitation but survived and was apparently undamaged. One could hardly expect ill effects upon the newborn with delivery planned to be completed within 8 minutes of induction of pentothal anesthesia. The records are not adequate enough to show the time interval between induction of anesthesia and delivery of the child but it is believed that 8 minutes was rarely exceeded and most often not nearly approached.

In the series, there were 10 infant deaths for an uncorrected total fetal mortality rate of 2.86 per cent. The infant mortality rates at Hermann Hospital for 1945 and 1946 during which years the sodium pentothal series was obtained are compared in Table XVII with figures from the current series. Since there was a certain amount of selection in the pentothal series, the infant mortality rates are not exactly comparable to the rates for the individual calendar years.

Of the 10 infant deaths in this series 4 were stillborn. Only 1 was macerated, antenatal death occurring in a prolonged pregnancy with an excessive sized erythroblastic fetus while the remaining 3 intrapartum deaths were due to premature separation of the normally implanted placenta (2 cases) and to prolapse of the umbilical cord associated with transverse presentation of the fetus.

One of the 6 neonatal deaths has already been mentioned in connection with resuscitation the child being born alive in apparently good condition requiring no resuscitation and 6 hours later being found dead in its crib presumably due to suffocation. In 1 instance, the patient was admitted directly to the delivery room and immediately delivered, without analgesia, by low forceps extraction. The umbilical cord was once around the fetal neck, the fetus had aspirated meconium and survived 6 hours. Another was delivered by easy low forceps extraction with poor application of the forceps. Demerol and hyoscine had been given 70 minutes before delivery much meconium had been passed in the terminal part of the first stage of labor the umbilical cord was once around the fetal neck and the

TABLE XVII.—INFANT MORTALITY RATES IN 350 CASES DELIVERED BY INTRAVENOUS SODIUM PENTOTHAL ANESTHESIA COMPARED WITH THE HOSPITAL'S RATES FOR 1945 AND 1946

	Year 1945 per cent	Year 1946 per cent	Current series per cent
Total gross fetal mortality	4.66	4.50	2.86
Total stillborn mortality	56		4
Total neonatal mortality		44	7

child lived only 3½ hours. It appears that in these 2 cases the loop of cord about the fetal neck was responsible for fetal distress, yet in 4 other instances its presence was associated with moderate resuscitation in 2 with the necessity for little resuscitation whereas in 54 more such instances the child required no resuscitation and was born alive in good condition. One child with serious erythroblastosis fetalis succumbed 12 hours after delivery. The remaining 2 neonatal deaths are attributable to traumatizing delivery by breech extraction. One weighed 10 pounds 10 ounces, required a long and difficult extraction lived 9 hours, and at autopsy showed cerebral hemorrhage. The final case was one of breech position in which the breech was decomposed with difficulty and extracted. This child lived only 5 hours and autopsy showed atelectasis and confirmed the fracture of one leg. There is no reason to assume that pentothal anesthesia was in any way the cause of any of these infant deaths.

There were no maternal deaths.

In conclusion we are not claiming any outstanding advantages for intravenous sodium pentothal anesthesia even in selected vaginal deliveries and are neither using nor recommending it as a routine obstetrical anesthetic. However, in our hands it admirably solved an embarrassing anesthetic situation. As used in a small series and in 2 per cent solution we have found it safe for mother and child. Its margin of safety seems to be such that a careful obstetric resident can quickly master the technique of its administration and can give it with little risk to patients. As such, it appears to be ideally adaptable to emergency obstetrical use but perhaps not to the casual

anesthetist. We are continuing to employ it in this manner and are convinced that it has a definite and permanent place in obstetrical anesthesia.

ANDROLOGIC ENDOCRINOLOGY

Correlation of Clinical Symptoms, Urinary Hormone Excretion and Testicular Cytology

JOSEPH W. GOLDZIEHER, M.D., and E. C. HAMBLIN, M.D. F.A.C.S.

Durham, North Carolina

THE diagnosis and classification of testicular failure (13) requires consideration of the dual function of the testis from the standpoint of etiology, pathology, hormonology, and clinical symptoms. Several groups of workers have correlated recently these features of patients with intrinsic testicular disease.

Heller, Nelson and Roth (6) employed the term "functional prepubertal castrates" to describe patients with agenesis, hypoplasia or preadolescent atrophy of the testes and with wolffian duct remnants (epididymis and vas deferens). The testes of these patients are completely lacking in both functional seminiferous and androgenic tissue. Accordingly there is azoospermia and failure of development of the sexual characteristics (change of voice, appearance of body and genital hair and growth and maturation of the genitalia). The urinary excretion of 17 ketosteroids and estrogens is low or low normal and the urinary excretion of gonadotropins is characteristically increased due to compensatory pituitary hyperactivity. Although delayed epiphyseal closure may result in eunuchoid proportions these patients are of normal or short stature.

Klinefelter and associates have described another group of patients with partial testicular hypoplasia or atrophy. The subsequent studies of Heller and Nelson (5) have defined the clinical, pathologic, and hormonal characteristics of the entire syndrome. There is total destruction of the seminiferous apparatus with partial or no damage of the androgenic elements. Azoospermia is invariably present. Androgenic function may be normal

or severely deficient. The urinary excretion of 17 ketosteroids and estrogens ranges from normal to very low levels and that of the gonadotropins always shows compensatory elevation. A significant number of these patients has gynecomastia. The habitus ranges from eunuchoid to normal. This group of workers has presented a concordance of clinical symptomatology, testicular histology, hormone excretion and present concepts of hormonal interrelations of the testis.

The 8 patients reported by us illustrate some of the remaining discrepancies in current concepts of testicular function and pathology.

METHOD OF SELECTION AND STUDY OF PATIENTS

The workup of each patient included a complete history and physical examination, routine blood and urine studies, determination of the basal metabolism, roentgenograms of the sella turcica and of long bones for osseous age determination, special blood chemistry as indicated, testicular biopsy, and urinary hormonal studies. The testicular tissue obtained at biopsy was fixed immediately in Bouin's fluid, embedded in paraffin, sectioned and stained with hematoxylin-eosin and with Masson and Mallory stains, reticulum stains were done when indicated. Urinary hormonal studies were based on a minimum of 4 to 6 consecutive 24 hour specimens. There were isolated 17 ketosteroids by extraction with carbon tetrachloride (7) and by purification with Girard reagent; values were determined photoelectrically by the color reaction with m-dinitrobenzene (8, 16); the results are expressed as milligrams per 24 hours. In patient 8 the Osting method for 17 ketosteroids was used. Gonadotropins were determined by a modification of the method of Heller and

From the Endocrine Division, Duke University School of Medicine and Duke Hospital.

Part of the expenses of this study was defrayed by grants to one of us (F. C. H.) from the Research Council of Duke University and from Ayerst, McKenna and Harrison, Ltd.

Chandler (4) devised by Salmon in our laboratory. The method involves dialysis and alcohol precipitation of refrigerated 24 hour specimens, dehydration, extraction and bioassay employing immature female rats; the results are expressed as rat uterine units, rat ovarian units and gross corpora lutea units per 24 hours.

PROTOCOLS OF PATIENTS

Patient 1 This 34 year old farmer entered the hospital because of bilateral inguinal hernias and varicose veins.

The clinical history revealed that he had been always nervous and subject to palpitations, and that he experienced muscular cramps in the arms and legs. He had passed a year previously a renal calculus. There was nocturia of three to four times and occasionally enuresis. Maturation had been rather slow the ages at which his voice changed and pubic hair appeared were not recalled but he shaved for the first time at the age of 20 years.

The physical characteristics are shown in Figure 1a. The blood pressure was 10/76 millimeters of mercury. The skin had a dry, inelastic, almost senile appearance. There was no pectoral hair, the axillary and pubic hair was normal in amount and in distribution, the facial hair was confined to the upper lip and to the chin and it was very sparse. In the left lobe of the thyroid, there was a 3 centimeter firm nodule which subsequently was shown to be a fetal adenoma. There were bilateral inguinal hernias and varicosities of the legs. The penis measured 3.8 inches in length and 3.5 inches in circumference at the corona. The scrotum was somewhat underdeveloped. The testes measured 1.5 by 0.75 inches and were fairly soft. The prostate was of normal size and consistency. The height was 74 inches, the span 71.5 inches, and the ratio of the upper half to the lower half of the body was 35 to 30. The weight was 127 pounds.

Routine laboratory studies revealed normal blood and urine. The basal metabolic rate was -25 per cent. Roentgenograms of the chest and sella turcica were normal.

Examination of the seminal specimen which was cubic centimeter in volume showed no spermatozoa.

Urinary hormone data included a 17 ketosteroid excretion of 6.6 milligrams per 24 hours (normal 11 to 20 mgm. per 24 hours) and a gonadotropin excretion of 25 rat uterine units, 12 rat ovarian units, 4 rat corpora lutea units per 24 hours (normal values 6 to 10, 3 to 7, 0 to 2 units per 24 hours, respectively).

Histological studies of the biopsied testes showed that the normal architecture was grossly distorted by the loss of many seminiferous tubules as well as by a great hyperplasia of the Leydig cells (Fig. 2a). Some of the better preserved tubules showed a single layer of spermatogenic cells enclosed by a dense, bazy hyalinized basement membrane which had a

fibrillar structure or resembled closely Askanazy's degeneration seen in tuberculous meningitis (Fig. 2b). Twisted columns of dense hyaline material represented the end stages of tubular deterioration. In some areas there was an increase in the number of blood vessels and some of the arteries appeared unusually thick walled. The remainder of the tissue showed a diffuse or nodular hyperplasia of the Leydig cells. In some areas the Leydig cells are greatly hypertrophied. Often they were arranged in cords or sheets and in these areas there was fair uniformity of appearance; the cell size was relatively normal and the cytoplasm thready and deep-staining with a peripheral pale or almost foamy zone (Fig. 2b). The cell boundaries appeared very indistinct. In other areas small groups of cells were supported by a delicate fibrillar stroma; these cells usually showed a foamy cytoplasm. In still other areas groups of very small Leydig cells with proportionately small but vesicular nuclei were found; the cytoplasm of these cells stained very densely. There were occasional regions in which the size of the cells showed remarkable variation even in a small field. Some of the nuclei were gigantic and rather irregular in outline with a dense granular chromatin network. The nucleoli were very prominent. Golden pigment was found in the cytoplasm of some cells but no crystalloids were present.

In summary the clinical evidence of hypogonadism was manifested by the eunuchoid build, the scanty body hair and very sparse beard, the senile skin and the small testes. The nervousness, muscular cramps and urinary frequency possibly may have been symptoms of androgenic failure. Azoospermia was present. The hormonal studies showed a 17 ketosteroid output of less than half the normal value whereas the urinary excretion of gonadotropin was approximately twice the maximum normal level. Despite these findings (highly suggestive of Leydig cell failure) the testes showed massive Leydig cell hyperplasia; moreover large numbers of these cells appeared entirely normal when studied by available histological methods.

Patient 2 This 18 year old millworker entered the hospital because of a slipped femoral epiphysis.

The clinical history revealed that he was the tallest member of his family and that he had always been thin. His voice changed at 14 years of age and pubic hair appeared at 17 years. No axillary hair had appeared and he had not shaved. He claimed normal heterosexual interests but had not had sexual intercourse. His height was 58 inches at 5 years of age and 70 inches at 18 years; he subsequently grew 4 inches in the following year and one-half

The physical characteristics are shown in Figure 1b. The blood pressure was 105/75 millimeters of mercury. There was poor muscular development and the joints were loose and hyperextensible. A slipped femoral epiphysis was demonstrated. There was no facial or axillary hair and the pubic hair was very scanty. The penis measured 6 inches in length and 5 inches in circumference at the corona. The scrotum was well developed. The testes measured approximately 1.0 by 0.75 by 0.75 inches. The prostate was normal in size and in consistency. The height was 74 inches, the span was 74 inches, and the ratio of the upper half to the lower half of the body was 32 to 42. The weight was 114.5 pounds.

Routine laboratory studies revealed normal blood and urine. The serum cholesterol was 173 milligrams per cent. The basal metabolic rate was -4 per cent. Visual fields were normal. A roentgenogram of the chest was normal. Roentgenograms of the skull showed a bridged sella turcica, absence of the frontal sinus and very few mastoid air cells. The osseous age was +10 to -14 years at the chronological age of 18 and was +14 to -16 years at the age of 19.5.

Examination of the seminal specimen, 0.5 cubic centimeter in volume, showed no spermatozoa.

The urinary hormone data included a 17 ketosteroid excretion of 11.3 milligrams per 24 hours and a gonadotropin excretion of 25 rat uterine units, 20 rat ovarian units, and less than 10 corpora lutea units per 24 hours.

Histological studies of the biopsied testes showed that the general architecture of the tissue was well preserved (Fig. 3c). The tubules were of normal size. The basement membrane was normal in the majority but in a few tubules it showed slight thickening and hyalinization. Within the tubules there was only a single layer of cells among which Sertoli cells were conspicuous (Fig. 3d). No unequivocal spermatogonia or spermatid stages were found. In some areas and usually near the periphery of the biopsy specimen the tubules were slightly distended by basophilic concretions which were granular or concentrically ringed, and contained occasional minute particles of highly refractile material. These masses compressed the tubular lining to a single layer of flat cells with dark, almost pyknotic nuclei and in advanced stages of the lesion caused disintegration of the tubular wall. The stroma was of delicate, fibrillar character. The Leydig cells were ample in number and were scattered diffusely throughout the stroma in groups of 3 to 10 cells. The majority was of normal size but occasionally hypertrophied cells collected in groups which attained the size of a tubule. A fair proportion of the Leydig cells had a milky or foamy cytoplasm but there were many cells which had an almost homogeneous, indistinct weakly acidophilic cytoplasm (Fig. 3d). The nuclei were of normal size oval in contour and showed the usual diffuse chromatin network. The nucleoli often were unusually prominent. No pigment or crystalloids were seen and no vascular changes were observed.

In summary, the clinical evidence of hypogonadism of this patient consisted of eunuchoid build, retarded development of scanty pubic hair, absence of beard or body hair, poor muscular development, small testes (with a large penis) and delayed ossification of the long bones. Azoospermia was present. The 17 ketosteroid value of 11.3 milligrams per 24 hours just fell within the lower limits of normal and the gonadotropin output was twice the maximum normal level (practically identical with patient 1). Despite this 17 ketosteroid level which was almost double that of patient 1, there were actually far fewer Leydig cells present and these occurred in small groups and strands rather than in the hyperplastic masses seen in the first patient.

Patient 3. This 17 year old student entered the hospital for the investigation of small testicles.

The clinical history revealed that pubic hair appeared at approximately 12 to 13 years of age. He shaved at the age of 17 years and he has shaved once or twice per week since that time. His physical strength always had been poor. The sexual outlook and activity were said to be normal.

The physical examination showed a definitely feminine habitus and the patient appeared somewhat younger than his age. The voice was adolescent in character and it continued so for several years. The beard and body hair were very sparse; there was moderate axillary hair and scanty pubic hair of feminine distribution. The nipples were prominent and erectile. The hips were wide. The penis was about three fourths of normal size. The scrotum was well formed and the testes were one half normal size and were soft in consistency. The prostate was approximately one half inch in diameter. The height was 69.5 inches, the span was 71.5 inches, and the ratio of the upper half to the lower half of the body was 35 to 34.5. The weight was 135 pounds.

Routine laboratory studies revealed normal blood and urine. Basal metabolic rate ranged from -13 to -23 per cent. The visual fields were normal. Roentgenogram of the sella turcica was normal. The epiphyses of the long bones were closed.

Examination of the seminal specimen, which consisted of a few drops of fluid, showed no spermatozoa present.

The urinary hormone data included a 17 ketosteroid excretion of 18.4 milligrams per 24 hours and a gonadotropin excretion of 60 rat uterine units, 35 rat ovarian units and 7 rat corpora lutea units per 24 hours.

Histological studies of the biopsy tissue from the testes showed that the normal testicular architecture was entirely lost. The tissue consisted of irregular areas of condensed stroma in which the remnants

of seminiferous tubules remained visible as thickened hyalinized basement membranes surrounding lumens filled with debris or occasionally with a few Sertoli cells. Some small homogeneous areas indicated the site of completely degenerated tubules. The stroma contained many engorged vessels of all sizes which were in close proximity, indicating condensation. There was massive nodular as well as medullary hyperplasia of the Leydig cells (Fig. 3a). In some areas these cells were distributed diffusely in large numbers among the other stromal elements elsewhere discrete nodules surrounded by concentrically flattened and compressed cells were present. The largest of these nodules measured 0.8 millimeter in diameter and was visible easily with the naked eye. The Leydig cells which were scattered diffusely throughout the tissue were generally of normal size with pale foamy cytoplasm and round or oval vesicular nuclei. No lipofuscin or crystalloids were seen (Fig. 3b). On the other hand, the cells within the hyperplastic nodules had a far different appearance. There was no longer a uniformity of cell size for many of the Leydig cells were very large and some of their nuclei were almost double normal size. An occasional foamy or almost clear cell could be seen, but the vast majority showed an intense eosinophilia, sometimes with a narrow clear zone at the extreme periphery of the cytoplasm (Fig. 3c). With the Masson stain the cytoplasm of these cells varied in color from steel gray to rose violet. Within these hyperplastic nodules numerous blood filled capillaries were present, but no other vascular changes were noted.

In summary the clinical evidence of hypoadrogenism of this patient consisted of scanty facial and body hair, an adolescent voice, poor physical strength, a small penis, testes and prostate. The habitus was definitely feminine. Azoospermia was present. Hormone studies showed a 17 ketosteroid output of 18.4 milligrams per day (a value near the upper limits of normal). Despite this value, the gonadotropin output was 60 rat uterine units per day (approximately 6 to 10 times normal excretion and representing the largest value in this entire group of patients). The Leydig cells showed massive, diffuse and nodular hyperplasia. Although a very large proportion of the cells (far more than in patient 1) showed abnormal cytology the 17 ketosteroid output was near the upper limits of normal. Finally despite this 17 ketosteroid output and histological evidence of Leydig cell hypertrophy and hyperplasia, clinical signs of androgen deficiency were unmistakable.

Patient 4. This 18 year old college student entered the hospital for the treatment of bilateral gynecomastia.

The clinical history revealed that he had noted the development of a subareolar lump in one breast and 6 months later a similar change occurred in the other breast. The hard nodules had regressed slightly with time. Pubic hair appeared at the age of 16 years. He shaved at 17 years and he has shaved once or twice a week since that time. His sexual drive was not very marked.

Physical examination showed a tall slender gracile build of somewhat feminine type. There was bilateral gynecomastia with an increase in both glandular and adipose tissue. There was minimal axillary and facial hair and there was almost no body hair. The pubic hair was scanty and of feminine distribution. The penis measured 3.5 inches in length and 3 inches in circumference at the corona. The scrotum was well developed. The testes measured 1.5 by 0.75 by 0.75 inches and were moderately firm. The prostate was small. The height was 70.5 inches, the span was 72.5 inches and the ratio of the upper half to the lower half of the body was 34.5 to 36.0. The weight was 160 pounds.

Routine laboratory studies revealed normal blood and urine. The basal metabolic rate was -7 per cent. The sella turcica and sinuses were normal on roentgenologic examination. The osseous age was 15 years.

Examination of the seminal specimen, which was 3 cubic centimeters in volume, showed 10,000,000 spermatozoa per cubic centimeter. Fifty per cent showed normal motility and 72 per cent showed normal morphology.

The urinary hormone data included a 17 ketosteroid excretion of 11.0 milligrams per 24 hours and a gonadotropin excretion of 5 rat uterine units, 5 rat ovarian unit and less than 3 corpora lutea units per 24 hours.

Histological studies of the biopsy specimen from the testes showed that architecture was fairly well preserved (Fig. 3d) although there was a great deal of interstitial hemorrhage and serous exudate. There was no condensation of the stroma and no peritubular fibrosis. A few completely hyalinized tubules and some areas of incipient hyalinization were seen, but for the most part the basement membranes were thin and delicate. The Sertoli cells were very prominent due to the scantiness of the spermatogenic cells. All stages of spermatoozoal maturation could be seen in some of the other tubules. The Leydig cells occurred in groups which were usually of normal, but sometimes of increased size there was no evidence of condensation in these hyperplastic areas (Fig. 3d). Elongated small transitional cells with homogeneous cytoplasm were fairly numerous. Most of the true Leydig cells had a vacuolated or foamy cytoplasm they did not show the densely staining, hazy cytoplasm of cells described in patients 1 and 2. No pigment or crystalloids were found within the cells. The nuclei were fairly dense and the nucleoli seldom visible. No vascular changes were observed.

In summary this patient presented a eunuchoid habitus, feminine contour and bi-

Fig. 1 a, Patient 1; b, patient 2; c, patient 5; d, patient 6; e, patient 7; f, patient 8.

lateral gynecomastia. Pubic hair appeared late; he shaved infrequently and the body hair was very scanty. The penis was of normal size but the testes and prostate were small. Normal spermatozoa were present in the seminal fluid. The 17 ketosteroid excretion (11 mgm per day) was at the lower limit of normal; gonadotropin excretion was normal. The testicular biopsy showed a slight increase in the number of Leydig cells and definite regression of the spermatogenic elements even in the absence of elevated gonadotropins.

Patient 5. This 16½ year old schoolboy entered the hospital because of a slipped femoral epiphysis.

The clinical history showed that he "always" had been overweight and tall for his age. Pubic hair appeared at 13 years. The voice had not changed. Heterosexual interests had not developed.

The physical characteristics are shown in Figure 1c. The blood pressure was 130/90 millimeters of mercury. There was no facial, axillary or body hair and the pubic hair was scanty and of feminine distribution. The penis measured 2.5 inches in length and 3 inches in circumference at the corona. The testes

were 0.5 by 1 by 1 inches and 0.75 by 1 by 1 inches in size. The prostate was small. The height was 70 inches, the span was 74 inches, and the ratio of the upper half to the lower half of the body was 34 to 36. The weight was 232 pounds.

Routine laboratory studies revealed normal blood and urine. The basal metabolic rate was -8 to -11 per cent. The blood sugar was 97 milligrams per cent; the serum cholesterol was 165 milligrams per cent. The sella turcica appeared normal. The osseous age was ± 15 years.

Examination of seminal specimens, which had volumes of 0.5 cubic centimeter, showed total spermatozoal counts of 65,000,000. Ninety-five per cent of the spermatozoa had normal cytology; 50 per cent showed motility and normal motility was present in 20 per cent.

The urinary hormone data included a 17 ketosteroid excretion of 10.2 milligrams per 24 hours and gonadotropin excretion of less than 2 rat uterine ovarian or corpora lutea units per 25 hours.

Histological studies of the biopsy tissue from the testes showed that the architecture of the tissue was well preserved. The tubules were normal in size and in many of them all stages of spermatogenesis appeared. Many of the tubules showed a hyalinized basement membrane and in some areas there was an increase in peritubular hyaline connective tissue.

Fig Photomicrographs of testicular tissue and b, Patient and d, patient a.

Elsewhere the stroma had a delicately fibrillar character. The universal scarcity of Leydig cells was very remarkable. They appeared on or two cell at a time in the areas of loose interstitial tissue; none of the usual small aggregates of cells was seen. The Leydig cells themselves were uniformly small. The cytoplasm was often foamy but sometimes stained a homogeneous pink with eosin. No pigment or crystalloids were present. The nuclei varied from homogeneously dense to vesicular in appearance. No vascular changes were noted.

In summary this obese patient presented a feminine eunuchoid habitus, scanty pubic hair, an adolescent voice, small penis, testes and prostate, and decreased seminal volume, motility and total count, although the spermatozoal count per cubic centimeter was normal. Both 17 ketosteroid (10.2 mgm. per day) and gonadotropin excretion (less than 2 rat uterine units per day) were definitely

Fig. 3. Photomicrographs of testicular tissue. a, b, and c, Patient 3 d, patient 4 e, patient 7

low yet relatively few small Leydig cells (even with a low gonadotropic stimulation) secreted more 17 ketosteroids than the hyperplastic overstimulated cells of patient 1

Patient 6 This 14 year old negro boy consulted the Endocrine Clinic because of a 40 pound weight gain in 6 months.

The clinical history showed that he always had been somewhat overweight, and that he had a voracious appetite and a marked craving for sweets. Asthma had been present since the age of 7 years. Pubic hair appeared at 13 years. No erections or nocturnal emissions had been noted. Psychiatric examination was normal.

The physical characteristics are shown in Figure 1d. The blood pressure was 150/90 millimeters of

mercury. The axillary hair was scanty the pubic hair abundant. There was no facial or body hair. A nodule of glandular tissue about 1.5 inches in diameter was present in the ample fat tissue of each breast. The penis measured 3.5 inches in length and 3.5 inches in circumference at the corona. The scrotum was well developed. The testes measured 1.75 by 1.25 by 1 inches and 2.0 by 1.25 by 1 inches and were of normal consistency. The height was 66.25 inches. The span was 72 inches. The ratio of the upper half to the lower half of the body was 31 to 35.25. The weight was 183 pounds.

Routine laboratory studies revealed normal blood and urine. The basal metabolic rate was +6 and +15 per cent. The visual fields were normal. Skull roentgenograms showed slight bridging of the sella turcica, normal frontal and rudimentary mastoid sinuses. The osseous age was normal.

An epididymal puncture showed an absence of spermatozoa.

The urinary hormone data indicated a 17 ketosteroid excretion of 7.3 milligrams per 24 hours and a gonadotropin excretion of less than 3 rat uterine ovarian, or corpora lutea units per 24 hours.

Histological studies of the biopsied testes (Fig. 4a) showed that the architecture of the testis was well preserved. The tubules were of normal size the basement membranes were delicate and of normal thickness save for occasional hyaline areas. Sertoli cells were present in normal numbers but there was a marked decrease in the spermatogenic elements. Small numbers of spermatogonia, occasional spermatocytes and in a few tubules spermatids were noted. The stroma showed a patchy increase in the form of widened bands of intertubular tissue. The stroma, even in these areas, was delicate and fibrillar in character with the elongated nuclei of fibrocytes being the chief cellular elements. Vesicular nuclei were seen infrequently the cytoplasm was pale and homogeneous. No pigment or crystalloids were seen and no vascular changes were observed.

In summary this obese, eunuchoid negro boy with bilateral gynecomastia developed pubic hair at the usual age. The osseous age, the penis, testes and scrotum were normal. Azospermia was present. The 17 ketosteroid excretion was normal for the age and the gonadotropin excretion was low. The testes showed decreased spermatogenesis and infrequent, small Leydig cells. This, then is the first patient to run true to expectation low gonadotropins low normal 17 ketosteroid excretion relatively few Leydig cells (but normal-sized testes) and minimal signs of hypogonadism. The eunuchoid habitus may have been a racial characteristic.

Patient 7. This 16 year old boy entered the hospital because of obesity and feminine appearance.

The clinical history indicated that the patient had been obese since childhood weighing 178 pounds at 10 years of age and 287 pounds at 13 years. The voice was high pitched at the age of 16. No body or facial hair had appeared, and no erections or nocturnal emissions had been noted. Increased craving for sweets, polydipsia and oliguria were present.

The physical characteristics are shown in Figure 1c. The blood pressure was 130/90 millimeters of mercury. Genu valgum and an increased carrying angle at the elbow were noted. There was slight hair on the chin and pubis. In addition to abundant adipose tissue there was a mass of firm glandular tissue about 2 inches in diameter in each breast. The penis measured 3 inches in length and 2.5 inches in circumference at the corona. The scrotum was small. The testes measured 1.0 by 0.75 by 0.5 inch. The height was 66.25 inches. The span was 67.9 inches. The ratio of the upper half to the lower half of the body was 34 to 35.25. The weight was 390.5 pounds.

Routine laboratory studies revealed normal blood and urine. The basal metabolic rate was +13 per cent. The electroencephalogram was normal and the intelligence quotient was 84. Visual fields showed questionable concentric narrowing. Roentgenogram of the sella turcica was normal. The osseous age was +10 to -13 years.

A seminal specimen could not be secured.

The urinary hormone data indicated a 17 ketosteroid excretion of 4.7 milligrams per 24 hours and a gonadotropin excretion of less than 3 rat uterine, ovarian, or corpora lutea units per 24 hours.

The histological studies of the biopsied testes showed that the architecture was somewhat normal. The tubules were uniformly small in size and the connective tissue was prominent and rather condensed, as if all the structures had decreased in size (Fig. 3c). There was some increase in the peritubular connective tissue and the basement membranes of the tubules had a highly refractile appearance, resembling somewhat the elastica interna of an artery (Fig. 4c). The seminiferous apparatus consisted chiefly of Sertoli cells although spermatogonia and occasional spermatocytes were present. Most of the tubules were solid cords of cells with masses of amorphous debris or cellular material in place of a lumen very rarely a tubule with a true lumen was seen. The stroma was increased throughout, and varied from a loose areolar network to fairly dense hyaline strands. The stromal cells were chiefly mature fibrocytes although some had vesicular nuclei. Fibroblasts were present in the areas of loose connective tissue. There were no cells which could be identified as Leydig cells. The largest vesicular nuclei were not associated with cells having definite boundaries or distinct cytoplasm. No vascular lesions were observed.

In summary this very obese boy of somewhat feminine habitus showed a delay in the development of genital hair a high pitched voice, gynecomastia, retarded ossification, a

sequent cultures were positive. Responses of this type are classified as failures.

2 Results In summarizing the overall results of therapy in the group of 465 cases, clinical and bacteriological cures were obtained in 34 per cent of the patients. In an additional 21 per cent, clinical improvement resulted, but the urines did not become sterile. Outright clinical failures occurred in 45 per cent of the 465 cases.

ANALYSIS OF RESULTS OF THERAPY

The failure to obtain any beneficial results in 45 per cent of the patients treated stimulated an inquiry into the causes of failure, to determine if the cure rate could be improved in patients treated in the future. The effects of streptomycin therapy were catalogued on the following points: (1) bacterial flora, (2) monobacterial versus polybacterial infections, (3) obstruction of urinary flow and presence of unsterilizable foci, (4) bladder paresis, as in paraplegia, (5) clinical diagnosis, (6) dosage, (7) duration of therapy and (8) presence of resistant organisms. The analysis will now be presented in this order.

1 Bacterial flora. The bacterial flora of the urinary tract infections comprising this series is shown in Table I. Eight hundred twenty-eight organisms representing 9 different species and a group of unidentified gram-negative bacilli are listed. Seventy-nine per cent of the total number are gram-negative bacilli. The remaining 21 per cent are gram-positive cocci, one third of which are the penicillin-resistant and sulfonamide-indifferent nonhemolytic streptococci. It is reiterated that a substantial majority of these bacteria are inhibited by concentrations of streptomycin which are easily maintained in the blood and urine by parenteral administration of the drug. Excluded of course are those bacteria which have acquired irreversible drug fastness, a constant feature of unsuccessful streptomycin therapy.

2 Monobacterial versus polybacterial infections. One hundred eighty-six patients (40%) had monobacterial infections, while in the remaining 279 (60%) the infection was polybacterial.

The outcome of streptomycin therapy in the 186 monobacterial infections is summa-

rized in Table II, according to causal organisms. The most gratifying results were obtained in infections due to *Escherichia coli*, paracolonic bacilli, and *Aerobacter aerogenes*. Fewer cures followed the use of streptomycin in infections due to other organisms. The results in infections caused by *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* are disappointing.

A comparison of the therapeutic effects obtained in monobacterial and polybacterial infections shows no appreciable difference between the 2 groups in the clinical results obtained. The greatest difference appears in the bacteriological results. Here it is noted that positive cultures persisted 16 per cent more frequently in the polybacterial than in the monobacterial group. This difference is statistically significant (1).

3 Obstruction of urinary flow and presence of unsterilizable foci. In an analysis of the results of therapy in patients with and without urinary calculi the contrast in the favorable results obtained in the noncalculus group with the unfavorable results obtained in infections complicated by calculi makes it clear that failures are an almost constant feature in the latter type of case. Needless to say, these figures are statistically significant (1). Accordingly streptomycin therapy should be withheld in the management of patients with symptomatic obstructive calculi until such time as the drug can be employed as part of the regimen aimed at removing the obstruction. Excepted of course are patients with actual bloodstream invasion when the drug may be required as a life-saving measure.

4 Bladder paresis. All paraplegias have some degree of nervous dysfunction of the bladder which is ordinarily designated as "cord bladder." The usual features are a weak detrusor action and an incompetent sphincter. These patients have urinary stasis as well as urethrovesical and vesicoureteral reflux.

Forty-two per cent of the patients in this series were paraplegics. In a comparison of the results obtained from streptomycin therapy in paraplegic patients and in nonparaplegic patients, no striking difference in the clinical cure rate was observed. However a

Fig. 4. Photomicrographs of testicular tissue. a and c, Patient 6 b and d patient 8.

penis of normal size, small testes and azoospermia. The 17 ketosteroid excretion was very low (4.7 mgm per day) and the gonadotropin excretion was also low. Extremely few Leydig cells were present. This patient also runs true to expectation (i.e. atrophy of

the Leydig cells, low gonadotropins and low 17 ketosteroids, probably entirely of adrenal origin). Under these circumstances the presence of bilateral gynecomastia is rather remarkable and it does not seem very likely that the hypofunctional testes should be held re-

sponsible. The presence of a normal sized penis and of clinical evidences of hypoandrogenism is worthy of note (see patient 2)

Patient 8 This 6 5 year old boy entered the hospital because of precocious statural and sexual development which was noted approximately 1 5 years previously

The clinical history showed that he always had been a "precocious" child however enlargement of the penis was not observed until the age of 5 years. Pubic and axillary hair and acne appeared at the age of 6 years. No voice changes were noted and there was no unusual sexual activity. During the observation his growth was as follows: At 6 5 years, the height was 52 inches the span was 51 inches and the ratio of the upper to the lower half of the body was 27 to 25. The weight was 50 pounds. At 7 years, the height was 54 inches the weight was 65 pounds. At 8 years the height was 57 25 inches the span was 57 inches and the ratio of the upper to the lower half of the body was 29 to 25. The weight was 78 pounds. His voice changed at 8 years.

The physical characteristics are shown in Figure 1f. There was no facial hair but acne was present over the forehead chin and nuchal regions. There was moderate axillary and pubic hair. The penis measured 4 5 inches in length and 3 5 inches in circumference at the corona. The scrotum was small. The testes measured 0 by 0.5 by 0.5 inch. The prostate was compatible with the penile size.

Routine laboratory studies revealed normal blood and urine Ca^{++} for a red blood cell count of 5.6 million. The basal metabolic rate was -4 per cent. The glucose tolerance curve was fasting, 82 milligrams per cent 0.5 hour 05 milligrams per cent 1 hour 127 milligrams per cent 2 hours 115 milligrams per cent 3 hours 115 milligrams per cent 4 hours 1 milligrams per cent. The blood chlorides were 592 milligrams per cent. The serum sodium was 14 milliequivalents per liter and the serum potassium was 4.0 milliequivalents per liter. The thyroid fields were normal. Intra venous urograms were normal. A roentgenogram of the sella turcica appeared normal. The frontal sinuses were absent at 6 5 years and present at 8 years. The osseous age was +10 to -3.

An epididymal puncture yielded no spermatozoa.

The urinary hormone data indicated a 17 ketosteroid excretion of 7.3 milligrams per 24 hours (normal values 2 to 4 milligrams per 24 hours) and gonadotropin excretion of 20 rat uterine units per 24 hours.

Histological studies of the biopsied testes showed that the architecture of the tissue generally was well preserved (Fig. 4b). Many tubules were immature but their appearance size and number were compatible with the patient's age. The basement membrane was highly refractile and there was slight hyalinization of some of the tubules. The Sertoli cells were numerous and spermatogonia were present in moderate numbers occasional cells resembling

spermatocytes were seen but spermatogenesis did not progress beyond this stage. In a very few tubules degenerative changes of a localized character were present but not in unusual numbers. Many of the tubules showed no lumens. The stroma was very scanty in some areas it consisted of a surprisingly dense hyaline connective tissue and in others of delicate scattered fibrocytes and fibroblasts. Occasionally larger round nuclei, suggestive of Leydig cells, were present but no fully developed Leydig cells were found (Fig. 4d). There were no aggregates of round nuclei indicative of potential Leydig cell development. No vascular lesions were noted.

In summary the height weight, ossification pubic, leg and axillary hair and penile and prostatic size were greatly advanced. Acne was present. There was, however no change in the voice, no facial hair no evidence of sexual activity and no seminal fluid. The 17 ketosteroid output (7.3 mgm. per day) was approximately double the normal value and the gonadotropin excretion was markedly elevated. The histological appearance of the seminiferous tubules and of the Leydig cells was consistent with the patient's age, apparently showing no response to the increased gonadotropin secretion. Androgen production of this patient was apparently extratesticular.

The clinical hormonal and cytologic findings of these 8 patients are summarized in Table I.

DISCUSSION

Clinical criteria of androgenic deficiency (3). The development of body hair is one of the most prominent clinical features of androgenic activity. Although racial and constitutional factors, as well as the activity of the adrenal cortex, play important roles in determining the amount and distribution of body hair the time of appearance of body hair yields important evidence of the state of testicular androgen production. In this respect, the hair of the face affords a very sensitive index of androgenic activity both the amount and distribution but particularly the time of appearance and rate of growth (easily measured by the frequency of shaving) are important. The characteristics of the facial hair obviously are subject to considerable individual variations. The pitch of the voice and the age at which the voice changes are also valuable evidence of an-

drogenic activity although apparently not quite as sensitive signs as beard growth

The *body habitus* is the result of complex hormonal phenomena acting over prolonged periods of time. The persistence of juvenile fat distribution is only one feature of androgenic deficiency. Retardation of epiphyseal closure and compensatory pituitary hyperactivity due to the intrinsic testicular failure appear to be the basis for the development of a eunuchoid habitus. Heller and Nelson (3) have shown however and we have confirmed their findings, that this hormonologic pattern does not result necessarily in a eunuchoid habitus. In the objective determination of eunuchoid build we have found that, in the absence of skeletal deformity the ratio of the upper to the lower half of the body reveals more often eunuchoid proportions than the ratio of height to span. The reason for this is quite obvious: measurement of the upper and lower halves of the body provides a direct comparison between the vertebral column (flat bones) and the long bones, whereas measurements of the height and the span include elements of each bone type (long bones, shoulder girdle and vertebral column) and therefore, these tend to dilute the anthropometric disproportion. Deformities, as genu valgum and kyphosis, however will render these measurements misleading unless the disproportion is very marked.

The *size of the penis* is often a very poor criterion of androgenic activity for rather severe degrees of deficiency may be present before diminutive size becomes significant. Furthermore, we have observed patients, with obvious evidence of hypogonadism who have normal or even large penes (patient 2). It is very interesting however that increase in penile size is one of the first responses to testosterone therapy.

The *size of the testes* bears only the crudest relationship to the clinical signs of testicular function. A small testis may show large numbers of highly active Leydig cells or a testis of normal size and consistency may show a great deficiency of hormone producing tissue.

The *size of the prostate* being unsuitable for exact measurement can be used only to judge gross deficiencies of androgen production.

Sexual interest activity and potency involve far too many psychological factors to be of clinical value in the majority of patients.

Muscular strength, endurance and stamina also are influenced greatly by psychological factors and should be evaluated with great caution. It is possible that objective measurements may yield worthwhile information especially in the evaluation of treatment of hypogonadism.

Other signs of androgen deficiency, as the dry senile appearance of the skin, muscular cramps, urinary frequency and nocturia,

represent severe degrees of androgen deficiency.

Biochemical criteria of androgen deficiency
The usual urinary hormonal studies provide a poor estimate of testicular function. The 17 ketosteroid excretion may be determined with considerable accuracy although it involves a long and tedious chemical procedure. However the data represent the combined 17 ketosteroid output of testes and adrenals. In relating these data to androgen production one assumes that the androgenic steroids form a more or less constant proportion of the total 17 ketosteroid output. This assumption is likely to be fallacious especially when a disturbance of the steroid metabolism is suspected. On the other hand present methods of androgen assay do not permit general clinical usage. The technique of chromatographic analysis has been applied recently to clinical practice if these data were quantified and correlated with androgenic activity they would provide a great advance in both qualitative and quantitative studies of steroid excretion.

Criteria of testicular pathology
Most of the careful cytological studies of the Leydig cells have been made in animals, partly because of the availability of material and partly because human autopsy material is frequently unsuitable for studies of the normal state (14). In fact only within the last decade, has it been realized that the 'textbook appearance' of testicular tissue is the exception rather than the rule (17).

There is a number of formidable difficulties in the interpretation of testicular pathology. Measurement of the total volume of tubules or Leydig cells of normal testes has been unsatisfactory even with the use of planimetric methods; the difficulty of making these estimates in the presence of pathological alterations is much greater (15). Far more important is the fact that there are no specific histochemical techniques for the measurement of hormone production of Leydig cells. The usual cellular stains (hematoxylin-eosin and Masson) reveal nonspecific cytological changes which are extremely difficult of correlation with functional activity. General lipid stains (Sudan and Nile blue) do not reflect the 17

ketosteroid content of the cells and are generally of little value. Stains for cholesterol-like substances, based on the Liebermann-Burchard reaction are more specific, but these are subject to the same criticism and they are often unreliable. The most valuable histochemical methods, apparently are based on the phenylhydrazine stain of Bennett (12). This method at first was thought to be specific for 17 ketosteroids, but some doubt recently has been expressed in this regard (1). It is unfortunate that this method as yet has not been applied to clinicopathological studies of testicular function.

The presence of the crystalloids of Renke apparently reflects to some degree the steroid-producing function of the Leydig cells. These odd-shaped bodies which stain with safranine, methyl violet, or other common dyes, give histochemical reactions of globulins, and not those of lipids. Their presence or absence, nevertheless, correlates fairly well with major changes in Leydig cell function.

It is agreed generally that the appearance of mitochondria and of the Golgi apparatus affords valuable evidence on the functional state of a cell. The material obtained by testicular biopsy is suitable for these studies (2) which would provide valuable information.

Descriptions of the histology of the testis (save for its spermatogenic elements) are scattered in the literature and are influenced often by histological studies of other species. Moreover the criteria of normalcy especially of the interstitial elements, are poorly defined. It is necessary to describe therefore, what are considered normal features of some testicular elements (2, 11).

The seminiferous tubules are bounded by a basement membrane which is strengthened by a layer of lamellated connective tissue. Both elastic and collagenous fibrils are present; the width of this band varies from about 1 to 4 microns. Within the tubule, spermatogenic and the Sertoli cells are found. The spermatogenic cells will not be discussed as detailed descriptions are found in any textbook of histology (11). The Sertoli cells, however are of considerable interest. The function of these cells is entirely unknown although they have been thought to be "supporting" or "nutri-

tive' elements supposition without any foundation of fact. Recently, estrogen producing, Sertoli cell tumors of the testis have been described (9) which may be the first objective evidence of the function of these cells (18)

The seminiferous tubules are supported in a loose stroma composed of collagenous fibrils, blood vessels, nerves, fibroblasts, macrophages, mast cells, and Leydig cells. The Leydig cells are scattered singly or in small groups of 4 to 10 cells throughout the stroma without any relation to tubules or blood vessels. The accumulations of cells as shown by Klinefelter and associates should not be regarded as normal and, in fact, were regarded as hyperplasia by the pathologist to whom they were shown. There are also smaller cells which are hard to distinguish from fibroblasts but their proximity to nests of Leydig cells suggests their developmental potentialities. The Leydig cells themselves are round, irregular or polyhedral in shape, about 14 to 20 microns in size, with a nucleus 5 to 8 microns in diameter, round and usually eccentric. The nuclear chromatin occurs in fine strands or granules and 1 to 3 large nucleoli usually are present. There is an attraction sphere around the nucleus and the Golgi apparatus is found immediately outside this region. Occasional binucleated cells are normally present. The cytoplasm is highly granular and contains numerous lipid globules (especially near the periphery) giving the cell a foamy appearance. Many of these fat globules are filled by nonlipid material with a surface coating of fat. Neutral fats, phosphatids, glycolipids, cholesterol esters, and steroids have been identified in the cytoplasm. There are found also the crystalloids of Reinke which may be seen also in the Sertoli cells. Lipofuscin, a brownish wear-and-tear pigment, appears after adolescence and generally tends to increase with age. Occasionally smaller cells with dense chromophile cytoplasm suggesting transitional forms from fibroblast like cells are observed.

With this discussion of normal cytology and of the distribution of Leydig cells in mind, it becomes possible to evaluate the alterations observed in our patients as well as in those of others. There has been an unusual hesitancy to make the differential diagnosis between

hyperplasia and condensation of the Leydig cells, although suitable criteria for this differentiation have long been established by pathologists.

Condensation implies the loss of parenchyma; the stroma does not disappear in proportion and there remain residual structures as an increased number of blood vessels, which are closer together than usual. One expects to find also remnants of degenerated tubules which do not disappear entirely but leave dense, hyalinized discs at their previous sites. With the collapse of the stroma, groups of Leydig cells are brought into closer proximity. These aggregates should have an alveolar type of structure with islands of irregular size and shape which are separated by variable amounts of stroma. In lesser degrees of condensation where these changes are not so marked the irregular distribution of the reticulum fibrils is evident and is quite different from the regular and even distribution of hyperplasia. Moreover it is manifestly impossible to consider unusually large aggregates of Leydig cells as condensation phenomena when they are embedded in loose areolar tissue (Fig. 3d).

Hyperplasia may be of diffuse or nodular variety (Figs. 2a and 3a). The former type develops from an overgrowth of the normal pattern with gradual coalescence of the groups to form a medullary cell mass with a delicate reticulum and very scanty stroma. There is obviously no difficulty in distinguishing this from condensation phenomena. With stronger irregular proliferation nodular conformations may appear. These also are differentiated easily from condensations because the stroma within the nodule is delicate and homogeneous instead of irregular and strand like, and because the tissues of the periphery often will show signs of compression, as concentric flattening of the adjacent stroma and parenchyma. The coexistence of condensation and hyperplasia is seen (Fig. 3a) and there has been no difficulty in distinguishing the two. We have felt, therefore, that it is wise to abstain from nonspecific terms as 'clumping'. The differentiation of condensation and hyperplasia is of great functional significance and every effort should be made to distinguish the two.

SUMMARY

In these 8 patients we have observed some agreement and many discrepancies between the expected and the observed findings. These may be summarized as follows:

1 *Leydig cells and hormone excretion.* In increased numbers of Leydig cells were associated with low (patient 1) or high (patient 3) 17 ketosteroid excretion or with normal (patient 4) or high (patients 1, 2, 3) gonadotropin excretion. Decreased numbers of Leydig cells were associated with very low (patient 7) low normal (patient 5) or high (patient 8) 17 ketosteroid excretion and with low (patients 6, 7) or high (patient 8) gonadotropin excretion. We confirm, therefore, the observation of Heller and Nelson (5) that there is no quantitative correlation between elevation of gonadotropic excretion and the 17 ketosteroid output.

2 *Clinical symptomatology.* Clinical evidence of hypoandrogenism was observed in the presence of low (patient 1) or high (patient 3) 17 ketosteroid excretion. Eunuchoid habitus was present with high (patients 1, 2) normal (patient 4) or low (patient 5) gonadotropin excretion or with increased (patient 1) or decreased (patient 6) numbers of Leydig cells. A large penis was noted with low normal (patient 2) or high (patient 8) 17 ketosteroids and a small penis with high normal 17 ketosteroids (patient 3).

Evidence of feminization was observed with high normal 17 ketosteroids and increased numbers of Leydig cells (patient 3) with low normal 17 ketosteroids (patients 4, 5) and with low 17 ketosteroids and few Leydig cells (patient 7).

Gynecomastia was observed in the presence of increased (patient 4) or greatly decreased (patients 6, 7) numbers of Leydig cells and yet with normal sized penis (patient 6). It was seen with normal (patient 4) or low (patients 6, 7) gonadotropin excretion or with low normal (patient 4) or low (patient 7) 17 ketosteroid excretion.

CONCLUSIONS

These 8 selected patients illustrate notable discrepancies between clinical evidence of androgenic activity, urinary hormone excretion, and testicular histology.

Alterations of the Leydig cells, as hypertrophy or hyperplasia *per se*, cannot be regarded as indicative of increased or even of normal secretory activity. It is possible that studies of mitochondria and Golgi apparatus, as well as the use of perfected histochemical techniques may provide in the future adequate cytologic criteria of endocrine cellular activity.

A COMPARATIVE STUDY OF THROMBOANGIITIS OBLITERANS IN WHITE AND NEGRO PATIENTS

H. A. DAVIS M.D. F.A.C.S., Los Angeles, California, and
L. D. KING M.D. New Orleans Louisiana

SINCE the appearance of the original studies of Buerger in 1907 concerning thromboangitis obliterans much has been written concerning this disease. It was believed at first to occur almost exclusively in Russian Jews, but it has since been seen in patients of varied racial origin.

The impression is widespread that this disease is rare in the negro and this would appear to be confirmed by the small number of cases of this disease in the negro which have been recorded in the literature. Our interest in this subject was aroused when we encountered an instance of thromboangitis obliterans in a negro woman. Because this is the first time that this disease has been observed in a female negro we shall describe later in this paper the salient clinical features presented by this patient. In addition to this however the purpose of the present paper is to present a comparative study of thromboangitis obliterans in white and in negro patients in a large general hospital in which the numbers of admissions of white and negro patients are approximately equal.

REVIEW OF THE LITERATURE

Gemmill (1925) was the first to report thromboangitis obliterans in the negro race. His patient was a male. Since no pathologic studies were presented the diagnosis must be considered as presumptive rather than proved.

In 1936 Smith reported a case of this disease in a male negro aged 39 years. The patient's Wassermann reaction was negative. Smith described no pathologic studies so that the diagnosis must be considered presumptive rather than proved.

Parsons in the same year (1936) also recorded the occurrence of this disease in a male

negro in whom there was a considerable admixture of white blood. In this patient there was also a history of luetic infection. Parsons stressed the difficulty of distinguishing thromboangitis obliterans from syphilitic endarteritis obliterans.

Scupham (1936) observed this disease in a male negro but he did not present adequate details concerning his patient.

Yater (1937) described the occurrence of thromboangitis obliterans in 5 male negroes. All the patients either had syphilis or had a history of a previous luetic infection. Two of Yater's patients required an amputation below the knee, and in the other 3 patients biopsies of the dorsalis pedis vessels were carried out. His patients all presented definite clinical and arteriographic evidences of occlusive peripheral vascular disease.

In 1941 Warshawsky pointed out that in all of the previously recorded cases in negroes there was a considerable likelihood of racial mixing with the white race. He described a case of thromboangitis obliterans in a full blooded negro male and accompanied his paper with convincing pathologic studies. Finally his patient presented no clinical or serological evidences of and gave no history of having had syphilis.

To summarize, therefore, 10 cases of thromboangitis obliterans in the negro have been recorded in the literature. All these patients were males. In 6 of the 10 patients the diagnosis was confirmed by pathologic studies. In 2 of the 10 patients there was no evidence of the presence of syphilis. Only 1 patient however could be considered to be a full blooded negro.

THE RELATIVE INCIDENCE OF THE DISEASE IN WHITE AND NEGRO PATIENTS

Our report is concerned with a group of white and negro patients who were seen in the

From the Department of Surgery, Louisiana State University and the Charity Hospital of Louisiana at New Orleans.

Dr. Davis is now associated with the Department of Surgery, College of Medical Evangelists, School of Medicine, Los Angeles, California.

Charity Hospital of Louisiana in New Orleans during a 15 year period extending from 1931 to 1945 inclusive. All patients over the age of 49 years were excluded from this series because of the increasing incidence of other forms of peripheral vascular disease in patients above this age. During this time there were 64 patients in whom the clinical or pathological diagnosis of thromboangiitis obliterans was made. Of these the diagnosis was made only on clinical findings in 48 patients and a clinical and pathological diagnosis in 16 patients. Of the 48 patients in whom the clinical diagnosis was made, 40 were white men 3 were white women and 5 were male negroes. Of the 16 patients in whom the clinical diagnosis was confirmed by pathological studies of the blood vessels 12 were white men 3 were male negroes, and 1 was a female negro. In this group of pathologically proved cases the ratio of negro to white patients was 1:3. In the entire series in this study there were 9 negro patients and 55 white patients which gives a ratio of 1:6.1

COMPARISON OF AGE INCIDENCE

Forty nine of the white patients were aged 30 to 49 years while in 6 the disease commenced between the ages of 20 to 29 years. In the negro patients 6 of the 9 patients were 30 to 49 years old and only 3 patients were 20 to 29 years old. However a statistical analysis was carried out in order to determine whether or not there was a significant difference in the age incidence between the white and negro patients. Examination of the statistics by the χ^2 test¹ with Yates modification showed no significant difference in the age incidence between the two groups.

DURATION OF SYMPTOMS

In order to determine whether or not the duration of symptoms was different in the two groups an analysis was made and showed that in the majority of the white patients (36) the duration of the symptoms was 5 years or less. In 19 of the 55 white patients the duration of symptoms was more than 5 years. Of the 9 negro patients 7 showed a duration of symptoms for 5 years or less while in only 2 of the 9

had the disease lasted longer than 5 years. Again application of the χ^2 test with Yates modification to the data revealed no significant difference between the two groups in duration of the symptoms and signs of this disease.

COMPARISON OF RESPONSE TO TREATMENT IN WHITE AND NEGRO PATIENTS

In the 55 white patients, conservative treatment was successful in 31 while it was necessary to perform major amputations of extremities in 19 patients and minor amputations in 5 patients. Of the 9 negro patients, major amputations were performed in 2 minor amputations in 6 while in only 1 patient was conservative treatment successful. When the patients requiring major and minor amputations—4 whites and 8 negroes—were placed in one group and those responding to conservative treatment in a second group—31 whites and 1 negro—comparison of the white and negro patients produced an interesting result. It was determined by means of the χ^2 test with Yates modification that a significant difference existed in this respect between the negro and white patients and that significantly more amputations were required in the negro patients than were required in the white patients with thromboangiitis obliterans. Was the proportion of minor amputations in the negro patients larger than that in the white patients? This question is answered by means of the χ^2 test with Yates modification. This test indicates that the number of minor amputations is very significantly higher in negro patients (6 patients) than it is in white patients (5 patients).

Conversely the χ^2 (Chi square) test with Yates modification indicates that there is a significantly higher ratio of major amputations to minor amputations in the white patients (19 patients) than in the negro patients (2 patients) in the present series. In comparing the success of conservative treatment and the need for surgical treatment in white and negro patients it was of interest to add to our series of negro patients the 9 negroes recorded in the literature on whom sufficient data were available. When the χ^2 test with Yates modification was applied to the data, our observation

¹Chi square test.

Fig. 1 Oscillogram of right leg showing arterial pulsation.

Fig. 2 Oscillogram of left leg (prior to amputation) There is an absence of arterial pulsation.

that the response of negro patients with this disease to conservative treatment is poorer than that of the white patients was confirmed. It was noteworthy that the incidence of major and minor amputations was significantly higher in negro patients than in white patients suffering from thromboangitis obliterans. The possible reasons for these differences in response to treatment between the two groups of patients will be discussed later.

Because no case report of thromboangitis obliterans in a female negro has appeared in the literature, we believe that a detailed record of this disease as observed by one of us (H. A. D.) in a negro female would be of interest.

CASE REPORT

J. E. Hospital No. L-40-54467 a negro woman aged 34 years, was admitted to the Charity Hospital of Louisiana in New Orleans in 1940. Her chief complaint was pain in the left leg. Her present illness started 4 years previously when the patient noted an intermittent pain in the left lower extremity. This pain was of a claudication type and increased when the extremity was used. At first the pain was relieved on rest but later the pain became continuous. Three years before admission the great toe of the left foot became gangrenous and had to be amputated. Three months before admission the patient's left leg felt cold and numb and became the site of a burning pain. These symptoms became progressively more severe, and, finally there appeared a

bluish discoloration of the toes and dorsum of the left foot.

A review of symptoms referable to other systems revealed the presence occasionally of precordial pain and slight dyspnea on exertion. During the past 3 months she had noted epigastric distress which occurred after meals. The patient stated that she vomited two or three times weekly. In her past

Fig. 3 Lateral roentgenogram of left leg. There is no evidence of calcification of the walls of the blood vessels.

Fig. 4. Cross section of the left posterior tibial nerve, shows thrombosis of the arteries and veins with recanalization. Perivascular fibrosis. $\times 32$. Hematoxylin and eosin stain.

history no serious illnesses were recorded. The patient denied having had syphilis although she admits that she may have had gonorrhea 1 year prior to the present admission. Her family history was noncontributory. The patient was unmarried but had been pregnant three times all of the pregnancies terminating in miscarriages. This suggests the possibility that the patient may have had syphilis. The social history of the patient contained some interesting facts. The patient was a heavy smoker having commenced smoking at the age of 13 years. The patient did not appear to be a full-blooded negro her skin being of a light chocolate color. Further inquiry however elicited from her the statement that her grandmother on the maternal side had been a white woman.

Physical examination revealed her temperature to be 98.6 degrees F, pulse rate, 90 per minute, respiratory rate, 20 per minute and the blood pressure, 140/80.

The patient was a well developed, well nourished negro woman of the stated age who did not appear to be acutely ill. The patient was complaining of pain in the left foot. Examination of the head, eyes, ears, nose and throat was negative. Her dental hygiene was good. The breasts exhibited no abnormalities. The lungs disclosed no unusual findings on physical examination. The heart was not enlarged its rhythm was regular and no murmurs could be heard. Abdominal examination revealed a slightly scaphoid abdomen but, otherwise, no abnormal findings. The pelvic organs were not examined.

The upper extremities did not present any abnormal physical findings. The right lower extremity was apparently normal. The pulsations of the right dorsalis pedis and right posterior tibial arteries were strong. The skin of the right extremity was found to be warm.

The most significant physical findings were present in the left lower extremity. The entire left leg was cold, and this coldness of the skin extended half way up the thigh. The second and third toes of the left foot exhibited a bluish discoloration and appeared to be firm and somewhat mummified in appearance. The great toe of the left foot was absent, and at its site there was the healed scar of a previous operation measuring approximately 6 centimeters in length. An irregular superficial ulcer measuring 2.5 centimeters in its greatest diameter and having a dry pink colored base was present on the dorsum of the foot immediately above the toes. The pulsations in the left dorsalis pedis and left posterior tibial arteries could not be palpated.

Oscillograms of the upper and lower extremities were made. The tracings obtained from the right and left arms were essentially normal and showed no significant differences. The oscillograms of the lower extremities were taken at the midpoint of the calf and at the midpoint of the thigh. The oscillogram of the right leg (Fig. 1) and right thigh revealed good pulsation of the blood vessels with fair amplitude of the waves. However the oscillogram of the left leg exhibited a complete absence of pulsations (Fig. 2). The oscillogram of the left thigh presented a decreased amplitude of the waves when compared with the oscillogram of the right thigh. Lateral roentgenograms of both lower extremities showed no evidence of calcification of the walls of the arteries (Fig. 3).

Laboratory findings. The hemoglobin value of the blood was 80 per cent. The red blood cell count was 4,300,000 per cubic millimeter. The white blood cell count was 13,013 per cubic millimeter. The differential count was 67 per cent polymorphonuclear leukocytes, 26 per cent lymphocytes, and 7 per cent monocytes. Urinalysis disclosed no abnormal findings. Urea nitrogen content of the blood was 71 milligrams per cent.

The flocculation and the Kolmer complement fixation tests were negative. The cerebrospinal fluid—Wassermann reaction—was negative. The cerebrospinal fluid was normal in all other respects.

Gastric analysis showed no occult blood. Free hydrochloric acid, 10 total acidity 40.

Electrocardiogram showed no definite evidence of myocardial disease.

The clinical diagnosis was (1) thromboangiitis obliterans involving the left lower extremity (2) pyrospasm.

October 24, 1940. The patient was admitted to the medical service.

October 29, 1940. The patient was transferred to the surgical service.

October 30, 1940. Left lumbar sympathetic block was carried out resulting in immediate warming of

statistically significant greater number of bacteriological cures occurs in nonparaplegic patients. As observed earlier by Petroff and Lucas, many paraplegic patients are temporarily benefited from streptomycin therapy although their urinary systems are not sterilized, and the effects are not necessarily permanent.

A word of explanation is warranted regarding the 25 per cent cures in paraplegics. The fact of the matter is that these cured patients are no longer paraplegics in the usual sense of the word. At the time of instituting streptomycin therapy for their urinary tract infections they were ambulatory with closed urinary systems and automatic bladders. By this means the factor of residual urine and urinary reflux is eliminated.

5 Clinical diagnosis The results of therapy may be classified according to clinical diagnosis. (a) As expected, the best results are obtained with streptomycin therapy in uncomplicated cystitis, pyelitis and pyelonephritis. (b) It is unfortunate that the presence of calculi in association with these conditions, sharply increases the failure rate, since here there is an urgent need for effective chemotherapy. (c) The presence of inadequately draining abscesses and fistulous tracts increases the percentage of failures. (d) When the lesions have progressed to the stage of hydronephrosis the chances of cure diminish significantly. (e) As noted in the 4 cases of neoplasm of the bladder, abnormal cellular

growths are nonsterilizable. (f) We have shown repeatedly (4, 6) that streptomycin does not reach the prostatic secretions in therapeutic levels following parenteral administration of the drug. This is borne out in analysis of the cases of urinary tract infections complicated by lesions in the prostate and seminal vesicles which have a high failure rate.

The duration of the infection has little bearing on the outcome of treatment. However, the reversal of urinary tract pathology in deep seated infections proceeds at a slow pace and a somewhat extended course of treatment may be necessary to achieve and maintain sterile urine cultures. This fact is illustrated by the

TABLE II—RESULTS IN MONOBACTERIAL INFECTIONS

Nonhemolytic streptococci							100				100

the skin of the left foot. The pulsations in the left dorsalis pedis artery became palpable for the first time. Repeated sympathetic blocks were done over a period of 2 weeks.

November 14 1940. The gangrene was extending to the dorsum of the foot.

November 16 1940. Under spinal anesthesia an amputation was carried out below the knee at the junction of the middle and upper $\frac{1}{3}$ of the leg. Bleeding was not excessive although a tourniquet was not applied.

December 21 1940. The wound was completely healed and the patient was discharged.

Pathological study. A dissection of the surgical specimen was performed. It was observed that the anterior tibial, the posterior tibial, and the peroneal blood vessels were thrombosed. The arteries, veins and nerves were closely bound together by adhesions which appeared to be inflammatory in origin. The arteries were dissected out along their entire length but even after thorough examination was carried out, disclosed no gross evidences of calcification of their walls.

Microscopic examination. Tissue sections were made at several levels through the tibial artery and vein of the amputated leg. Microscopic examination of the vessels at low magnification (Fig. 4) reveals that all the vessels are occluded by organized thrombi in which can be seen newly developed vascular channels. The vessels are bound together by dense fibrous connective tissue containing numerous lymphocytes plasma cells monocytes and foci of polymorphonuclear leucocytes. A striking feature of the microscopic picture was the appearance of numerous smaller blood vessels suggesting the development of a collateral circulation as a result of occlusion of the larger vessels. The internal elastic lamina of the arteries appeared to be intact. Microscopic examination at a higher magnification (Fig. 5) of the tibial artery showed the presence in its lumen of a cellular well organized thrombus infiltrated by lymphocytes plasma cells, and other mononuclear cells. The thrombus contained numerous endothelial lined spaces some of which contained fresh blood cells. The internal elastic lamina was intact. The media was somewhat fibrotic and was infiltrated to a moderate extent by mononuclear cells mainly lymphocytes and plasma cells.

Follow-up. The follow up of this patient presents points of interest. Two years after her operation she was operated upon for a typical duodenal ulcer proved by roentgenograms and at operation when a subtotal gastric resection was performed. On being questioned at this time the patient admitted that she had stopped smoking for several months after the amputation of her left leg but had resumed the habit. At the time of her admission to the hospital for treatment of the duodenal ulcer she was smoking 10 to 20 cigarettes each day. She had no symptoms of pain in the stump of her left leg nor in the right leg examination of which disclosed normally pulsating peripheral arteries.

Fig. 5. Cross section of the left posterior artery, shows organized thrombosis with recanalization and infiltration by mononuclear cells. $\times 80$. Hematoxylin and eosin stain.

ABSTRACTED CASE HISTORIES

It might be pertinent at this point to present briefly the findings in the male negroes who had thromboangiitis obliterans and in whom the diagnosis was proved by means of pathological examination of the surgically removed tissues.

1. F. M., 39 years, male, negro had pain in right calf the right foot became gangrenous there was absence of pulsation of the right popliteal artery Wassermann reaction was negative, and he gave no history of luetic infection. The patient was a smoker the right leg was amputated.

Pathological diagnosis thromboangiitis obliterans.
2. A. D., 26 years, male, negro had pain in right great toe. Wassermann reaction was negative and there was no luetic history the patient was a smoker right great toe was amputated. Pathological diagnosis thromboangiitis obliterans.

3. P. P., 36 years, male, negro had pain in right and left lower extremities and upper extremities. He was a smoker. Wassermann reaction was negative and there was no luetic history. He was repeatedly admitted to hospital when he had successive amputations of 5th toe of left foot (1933) the great toe of the right foot (1939) and the index finger of the right hand (1940). Pathological diagnosis thromboangiitis obliterans.

The 5 negroes in whom only a clinical diagnosis of thromboangitis obliterans was made might be briefly described.

1 L. J., 31 years, male negro, had pain in the left great toe with gangrene, amputation of toe. Wassermann reaction was negative and he gave no history of lues. Pathologic studies were inconclusive.

2 J. H., 30 years, male negro, had pain followed by gangrene of the 5th toe of right foot requiring amputation. No pathological studies were made. Wassermann reaction was negative but there was a history of luetic infection.

3 C. P., 40 years, male negro, had pain and edema of left lower extremity. He recovered under conservative therapy. No pathological studies were made.

4 O. F., 40 years, male negro, had pain and later gangrene of left lower extremity. Bilateral lumbar sympathectomy was done. Right great toe was amputated. No pathological studies were made. Wassermann reaction was negative and he gave no history of luetic infection.

5 C. R., 28 years, male negro, had pain in left lower extremities. There was absence of pulsation in left dorsalis pedis and posterior tibial arteries. Gangrene of 3rd, 4th and 5th toes of left foot required amputation of these toes. Wassermann reaction was negative. The pathological studies were inconclusive.

A survey of the literature on thromboangitis obliterans might suggest that this disease is extremely rare in negroes because up to the time of the present report only 10 instances of the disease have been recorded in the negro. In 6 of the 10 patients the diagnosis was confirmed by pathologic studies. In the present series 9 patients were negroes and in 4 pathological examination of the tissues verified the clinical diagnosis of thromboangitis obliterans. The fact that 9 of the 64 patients observed during a 15 year period were negroes suggests that the disease is by no means rare in this race.

What is the etiological significance of syphilis in the production of these vascular changes in the negro? In 8 of the 10 instances of thromboangitis obliterans in negroes previously reported in the literature syphilis was present. In 7 of the 9 negro patients with thromboangitis obliterans in this present series there were no serological or clinical evidence of luetic infection and no history of luetic infection. One patient gave a history of having had a syphilitic chancre and a second patient (J. E.) had had 3 miscarriages. We agree with Yater

in his conclusion that in view of the high incidence of lues in the negro race the association of this disease with thromboangitis obliterans in the negro is coincidental.

No significant differences in the age incidence and in the duration of the disease existed between the white patients and the negro patients.

The outstanding difference between the two groups lay in their response to treatment. Conservative treatment, that is, nonsurgical treatment was conspicuously less successful in negro than in white patients. The incidence of amputations was significantly higher in negro patients than in white. This lack of success of conservative methods of treatment in these patients was noteworthy and may be explained in several different ways.

1 The negro patient comes to the physician later for treatment than does the white patient. However this contention is not supported by a comparison of the duration of the symptoms in both groups. No significant differences were observed in this respect in the two groups.

2 The greater lack of cleanliness among negro patients may predispose to infection of the poorly vascularized tissues.

3 A comparison of the smoking habits of these negro and white patients was not possible in this study.

4 There may be a racial lack of resistance to this disease in the negro. If this were so the disease should occur more frequently than it does in this race. Indeed there is some evidence that the opposite may be true, namely that some degree of racial immunity to Boerger's disease may exist among negroes. Two facts would tend to support this view. First, the disease is less common in negroes. Second, in the present series of cases the incidence of minor amputations was significantly higher in the negro patients than in the white patients when compared with the incidence of major amputations.

SUMMARY AND CONCLUSIONS

A study is presented of 64 patients suffering from thromboangitis obliterans. In 16 of these patients the diagnosis was confirmed not only clinically but also by pathological examination of the tissues. Twelve of the 16 patients were

white men 3 were negro men and 1 was a negro woman

No significant differences were observed between the two groups with respect to the age incidence or to the duration of symptoms

The response to conservative treatment was poorer in the negro patients than it was in the white. The reasons for this difference have been discussed

The occurrence of thromboangitis obliterans in a female negro is reported for the first

time in medical literature The clinical diagnosis in this patient was confirmed by pathological studies of the tissues

A REPORT ON THE USE OF THE HARRIS TUBE

RODOLFO E. HERRERA, M.D. JOHN BRADFORD MILLET, M.D., and
GEORGE HUGH LAWRENCE, M.D. Boston, Massachusetts

SINCE the appearance of Harris' article describing his ingenious tube and his experiences with it as an instrument for decompression of the bowel there has not to our knowledge been sufficient trial of his tube. In the absence of more recent accounts by others, we felt that it would be of interest to report our early experiences with the Harris tube at the Massachusetts General Hospital.

The present report consists not of a selected number of cases, but on the contrary is an account of the first 30 cases in which we used the Harris type of intestinal suction.

We have to date been unable to obtain radio-opaque rubber tubing and have resorted to koroseal transparent plastic tubing $\frac{3}{8}$ inch in diameter. This tubing can be visualized on a dry x ray plate but is not visible by fluoroscopy. Its transparency is an aid to checking its function. The leading end is fitted with a hollow perforated metal tip¹ and a double thickness of condom is tied over this with two fine silk or cotton threads. After the mercury is introduced inside the inner bag and all the air is expressed, the other ends of the bags are similarly tied over an internal metal collar² placed 5 inches proximally in the tube. Six small holes about $\frac{1}{32}$ of an inch in diameter are then cut out of the side of the tube, with a pair of scissors, an inch apart just above the bag and the tube is ready for use. The unsalvageable parts of the tube cost 35 cents. We replace the tubing and the bags before reusing the apparatus. A double thickness bag has been resorted to following the accidents reported in Cases 5 and 6. Since using a double-thickness bag we have had no more ruptures with escape of mercury. Four cubic centimeters of mercury were used in most cases,

but we have had equal success with 2 and with 3 cubic centimeters.

We have employed the tube in the following manner. Surgical lubricating jelly is used, because mineral oil tends to weaken the rubber bag and the tube is passed through the nostril into the stomach and then left to progress at will. Mineral oil on the tubing at the nose level adds comfort to the patient and allows the tube to pass more freely. We have not found it necessary to place the patient on the right side or to feed the tube manually. The tube if left oiled and unattached at the nostril, has progressed of its own accord. Suction has been used only on the obstructed patients, and dietary restriction only when indicated clinically.

If the tube has failed to progress in the first 12 hours, we have used fluoroscopy to place the tip of the tube accurately at the pylorus. It has been our experience that if the tube has not passed the pylorus of its own accord, manipulation under the fluoroscope is also unsuccessful; however placing the tip of the tube at the pylorus is often rapidly followed by spontaneous passage into the duodenum.

Strapping the tube to the nose has always halted the progress of the tube, and removal of the tube has not been more difficult than when a double-lumen tube has been used. Cases 1 and 4 are interesting in this regard.

The table summarizes the results in the first 30 cases in which we employed this tube. We would like to state here that in only 2 or 7 per cent, of these 30 cases did the tube definitely fail to pass the pylorus within 24 hours and that at operation or at postmortem examination an adequate mechanical cause for failure was present in each case.

In 2 other cases the tube passed the pylorus only to be regurgitated later. Hiccupping Trendelenburg position and pulling on the tube by the patient were thought to be partially or completely responsible for these fail-

From the Surgical Services of the Massachusetts General Hospital.

¹The metal tip of a Miller-Abbott tube can be used here.

²We have had to make these collars of 14 inch brass drilled with No. 36 drill.

Fig. 1 Diagram of the construction features of the type of Harris tube used by the authors

ures. A double lumen tube with inflated bag might have been more successful. In the remaining 26 cases, or 87 per cent the Harris tube worked quite satisfactorily with only minor mishaps some of these we have encountered before with the Miller Abbott tube, and others we have learned to prevent.

SUMMARY OF CASES

Type of case	No. of cases	No. of cases requiring over 12 hrs. for passage of pylorus	Complications	No. of cases requiring manipulation under fluoroscope
Paralytic ileus	7	case 24 hours, cases failed	Cases 1, 3	without success tip placed at pylorus
Preoperative intubation for bursal resection			Cases 4, 5, 6	
Small bowel obstruction	7	case, 24 hours, case failed	Cases 7-8	tip placed at pylorus
Volvulus			Case 9	
Malfunctioning gastrostomy				

The following case reports are presented to show some of the difficulties and complications we have encountered in the use of the Harris tube.

CASE 1. M. C. 538219. This 50 year old woman entered the hospital with an irreducible proidentia of 2 weeks duration. The mass was the size of a foot ball and consisted of a protruding everted vagina containing bladder, bowel, and uterus. We were unable to correct the prolapse manually even with the

Fig. 2 Photograph demonstrating the redundant folds of the bag collapsed about the traversing tube and the pooled mercury. We feel that the ease with which the tube passes the pylorus is closely related to how well the air is evacuated from the bag in the process of constructing the tube.

patient in Trendelenburg position. Examination also showed a carcinoma of the left breast with axillary metastases, an anemia of 6 grams per cent hemoglobin, and a tensely distended abdomen with shifting dullness and some high pitched peristalsis. X ray examination showed a gas pattern consistent with paralytic ileus. A Harris tube was passed with ease, and the proidentia was reduced and strapped in place. Pentoneoscopy established the diagnosis of metastatic carcinoma, and 5,000 cubic centimeters of ascitic fluid were removed. Despite repeated attempts in the course of 48 hours the Harris tube could not be withdrawn. X ray film showed the tube to have reached the distal ileum with no kinks or knots. The tube was therefore allowed to pass completely into the gastrointestinal tract and 10 days later was withdrawn by rectal examination in a double bow knot.

CASE 2. L. C. 539927. This 60 year old man entered the emergency ward with paralytic ileus and vomiting which he had had for 7 days. A Harris tube was introduced, but several attempts at manipulation under the fluoroscope over a 72 hour period were ineffectual in passing the tube through the pylorus. The patient improved on chemotherapy and was found on x ray examination to have a craterized duodenal ulcer and later at laparotomy to have a

localized subhepatic abscess exerting extrinsic pressure on the stomach. These combined mechanical factors are considered sufficient explanation for failure of the tube to pass through the pylorus.

CASE 3. I. B. 539297. This 78 year old man entered the hospital with paralytic ileus and vomiting. A Harris tube was introduced but failed to pass through the pylorus despite three manipulations under the fluoroscope. The patient lost ground steadily and expired on the tenth hospital day. Post mortem examination revealed three abscesses in the peritoneal cavity and an extensive carcinomatosis originating in a large gastric lesion which mechanically obstructed the pylorus.

CASE 4. R. deS. 553005. This 73 year old woman had a large carcinoma of the hepatic flexure. A Miller Abbott tube was started but would not pass the pylorus even after manipulation under the fluoroscope and after the addition of 2 cubic centimeters of mercury into the balloon. A Harris tube made of soft rubber tubing was then used, which under the fluoroscope was seen to go through the pylorus immediately.

This tube descended 8 feet during the 24 hours that elapsed between its insertion and the time of operation. The patient died suddenly during the induction of anesthesia, and the tube could not be withdrawn post mortem.

CASE 5. A. P. 240258. This 48 year old woman was suffering from a carcinoma of the rectum and had a Harris tube passed preoperatively. After 2 hours the tube had made no progress and she was taken to be fluoroscoped. The tip of the tube was found to be in the third portion of the duodenum and the mercury scattered in the small bowel. After removal of the tube the single thickness bag was found ruptured. A new Harris tube with a double thickness bag was used without complications. The free mercury came out of the colostomy 8 days after operation. The patient apparently suffered no ill effects.

CASE 6. A. B. 539900. This was a 65 year old man who had been intubated with a Harris tube for decompression prior to resection of a sigmoid flexure neoplasm. On the seventh postoperative day the tube was removed and when withdrawn to the cardia, the single thickness bag ruptured allowing mercury to escape into the stomach. The patient suffered no untoward effects.

CASE 7. F. S. 547760. This 24 year old man was intubated with a Harris tube for small bowel decompression. He had had a strangulated inguinal hernia with small bowel obstruction for 4 days. Peripheral circulatory collapse dictated his being placed on shock blocks. Shortly before death, 48

hours after admission and small bowel resection, the end of the tube which had previously passed through the pylorus was found to have been regurgitated back into the esophagus. He had been afflicted with the hiccoughs and the effects of gravity with his coughing are considered to have been responsible for the final position of the tube.

CASE 8. E. D. 488067. This 17 year old girl had had an appendectomy and two subsequent laparotomies for acute small bowel obstruction during the 24 months prior to admission. She had been hospitalized by the dental service for an alveolar abscess and again developed acute small bowel obstruction, this time while in the hospital. A Harris tube was passed but was withdrawn 3 hours later in the operating room prior to ascertaining whether it had passed the pylorus. This case is included with those that failed to pass the pylorus.

CASE 9. C. M. 548680. This 39 year old man who had volvulus and strangulation of his small bowel was decompressed satisfactorily for 48 hours following the passage of a Harris tube. On the morning of the third day the tip of the tube was found to lie in the nasopharynx. It was not clear whether hiccoughing, with which the patient was afflicted, or his own attempt at removing the tube was responsible for this complication.

SUMMARY

An analysis of 30 cases in which a tube similar to the Harris tube has been employed is presented. In 87 per cent of these cases this tube functioned adequately. We feel that the Harris tube is a real addition to the physician's armamentarium. Its advantages are:

1. A rapid and spontaneous passage through the pylorus in a high percentage of cases.
2. A larger suction lumen allowing freer drainage than a double lumen tube.
3. A single lumen through which the attending nurse may irrigate the tube without the danger associated with irrigating the wrong orifice of a double lumen tube.
4. A smaller total diameter and hence a lesser discomfort to the patient than with a double lumen tube.

DIVERTICULA OF THE DUODENUM AND JEJUNUM

With a Report of a New Technical Procedure to Facilitate their Removal and a Discussion of their Surgical Significance

HOWARD MAHORNFR, M.D. F.A.C.S., and WENDELL KISNER M.D.
New Orleans, Louisiana

THE purpose of this paper shall be the discussion of known facts concerning duodenal and jejunal diverticula which have appeared in the literature. From this study of the literature and from our own experience we hope to evaluate the surgical significance of these diverticula. Thirdly we wish to discuss the technical features involved in operations for these lesions and report a new technical procedure which insures against overlooking any duodenal diverticulum at the operating table.

Important reports in the literary history of this subject are few before the advent of roentgenography. Most authors credit Chomel in 1710 with the first description of a duodenal diverticulum. In 1761 Morgagni described a duodenal diverticulum encountered at necropsy. This is relatively recent considering the long ages over which numerous individuals must have suffered from this sporadic lesion and it can be explained only by the fact that diverticula of the duodenum rarely are the direct cause of death. Until Case in 1913 first made the diagnosis in the living individual by roentgenography, practically all of the papers on this subject reported postmortem findings and viewed the clinical aspects only in retrospect. Sir Astley Paston Cooper is credited with being the first to describe jejunal diverticula encountered at autopsy (Ian Fraser). Sir William Osler (1881) also wrote on this subject and described a man aged 65 years who died of another cause but who at autopsy showed numerous (33) diverticula of the jejunum. For a long period of time, after his meals he had had crampy pains and loud borborygmi which Osler attributed to filling and

emptying of the diverticula.¹ Case in 1913 had diagnosed 4 cases of duodenal diverticula by fluoroscopic examination and demonstrated his findings in an exhibit at a meeting of the American Medical Association. He described the method used for ascertaining the presence of these duodenal defects in an article published in 1920. Forssell and Key in 1915 first removed a duodenal diverticulum surgically which had been diagnosed preoperatively by fluoroscopic examination. This was the first case in which a direct premeditated surgical attack had been made with the intention of removing a duodenal diverticulum known to be there prior to the operation. This was a very important landmark in the history of this subject and most papers refer to it as such.

In spite of the fact that duodenal diverticula are not rare surgical operations to remove or correct these defects are certainly not common. Most of the literature even of the present day consists of reports of 1 or 2 cases treated surgically. Articles dealing with operations for 3 and 4 cases are rare and in no instance have we encountered the report of over 4 cases in which operation was successfully carried out. The existing attitude concerning the surgical significance of duodenal diverticula is shown in numerous articles. For example Costello (1933) reported 6 cases, 3 of which definitely gave symptoms but only 1 patient was operated upon in order to relieve the symptoms. And Morton (1940) reported from the University of Rochester that primary duodenal diverticula had been diagnosed in 33 different patients but only 2 were operated upon and in only 1 of the 2 was the diverticulum successfully removed. In 19 duodenal di-

Although Osler was still at McGill University at the time that this paper was published, his literary style, which developed so beautifully in his later career, already was evident in this report.

Read before the Birmingham Surgical Society, Birmingham, Alabama, April 6, 1947.

From the surgical services of Dr. Howard Mahornfr, Baptist Hospital and Touro Infirmary, New Orleans, La.

some of them are huge but residual pooling of barium in the diverticulum is apparently a common finding and in our opinion should be an important distinguishing feature in judging whether operation for the diverticulum would actually relieve the symptoms. Roentgenographic studies to be thorough must include recumbent and lateral positions and pressure filling of the duodenum and in addition a serial roentgenogram taken in 6 hours to determine residual pooling in the diverticulum.

SEX

Studies found in the literature do not clearly distinguish a predilection of either sex to form these diverticula. Hahn collected 207 cases from the literature and estimated that 54 per cent were in women and 46 per cent in men. Spriggs and Marxer reported of 38 cases disclosed roentgenographically 20 were women and 18 were men. In 85 cases discovered roentgenographically Case found 60 per cent in women 40 per cent in men whereas the sex distribution of 55 cases reported by Centano was 15 women (33%) and 37 men (67%). Apparently the distribution is almost equal in the two sexes.

LOCATION

Most of the duodenal diverticula occur on the concave side of the descending portion. The majority of them occur in the region of the ampulla of Vater and for that reason they have been called 'perivaterian diverticula' by the French. When they occur on the second portion of the duodenum they either present into the head of the pancreas and are covered by it or more commonly originating in the perivaterian area, they lie posterior to the duodenum with a fundus extending even to the right of the duodenum giving the impression on roentgenographic study that they may be attached to the right border of the duodenum. Such apparently rarely if ever occurs. Diverticula of the second portion of the duodenum rarely ever protrude anterior to the head of the pancreas. There apparently are exceptions to this (Wilkie Baldwin). Next to the perivaterian area the concave inferior transverse portion of the duodenum is the site most often affected. The diverticula here

present upward and are covered by the transverse mesocolon and are associated with the ligament of Treitz. Diverticula apparently do not occur on the inferior border of the third and fourth portions of the duodenum. Diverticula occur even less frequently in the first portion of the duodenum. They are apparently rare there except as 'pseudo diverticula' caused by pouching due to contracture of an ulcer. However genuine diverticula do occur in the first portion of the duodenum and apparently from roentgenographic pictures presented in the literature they occur on the superior border more often than on the inferior. The following statistics bear out these statements. In roentgenographic studies of 5263 cases reported by Centano 55 patients showed duodenal diverticula. In 37 of the patients (67%) a diverticulum was found in the second portion of the duodenum. In 17 patients the diverticulum was situated in the third or fourth portion. All of the 15 diverticula discovered by Baldwin at necropsy were on the concave descending portion of the duodenum. The diverticula are more commonly found single but two or more may exist. In 70 per cent of those cases reported by Nagel the diverticulum found in the duodenum at necropsy was a single diverticulum. In 30 per cent of the instances 2 or more were found. Spriggs and Marxer reported that 84 per cent were single and 16 per cent were multiple. This was a roentgenographic study. In Baldwin's series of 15 necropsy cases 2 (14%) showed multiple diverticula. In 1 of our cases 3 diverticula were found at operation. 2 additional in the same case were missed. Multiplicity is an extremely important feature of course to the surgeon. He can expect to find more than 1 diverticulum in a sufficiently high percentage of cases to be always wary of missing others even after one has been disclosed and removed.

PATHOLOGY AND ETIOLOGY

Much of the older literature on this subject is concerned with the pathology and causes of duodenal diverticula. Indeed it would seem that the papers of least practical importance devote themselves largely to such a discussion. Various definitions and terms are associated

with these diverticula but now that the real importance, that is the diagnosis and relief of symptoms caused by these conditions, has become a realization these repetitious discussions seem highly pedantic. We however like other authors before us are tempted to repeat these definitions. Diverticula are generally divided into true and false true meaning those in which the wall of the diverticulum has all the layers of the duodenal wall false diverticula are those in which the muscularis is absent from the walls and in which there is a herniation of the mucosa through a defect in the muscularis making the diverticula walls consist only of mucosa and serosa or mucosa alone. In addition to this diverticula are divided into genuine and pseudo pseudo diverticula being relative pockets on the duodenum caused usually by contraction of an ulcer scar and genuine diverticula being out pouchings of a true or false nature beyond the usual limits of the duodenal confines. Also diverticula are sometimes divided into congenital and acquired which distinction is most hard to define since congenital diverticula existing soon after birth are extremely rare.

The diverticula themselves by far the majority of which are herniations of the mucosa or false diverticula are extremely delicate and thin walled soft and compressible. Usually the os of a diverticulum is quite large and obstruction of it is rare but the os is fixed by virtue of the fixation of the duodenum, and for that reason when a large diverticulum fills and the patient remains in the erect position retention of the contents may continue for hours. Emptying and filling of jejunal diverticula on the other hand must occur with equal facility. The jejunum being relatively unfixed in position undoubtedly swings and churns and changes position sufficiently often to prevent prolonged retention. This accounts for 2 important facts first a jejunal diverticulum more rarely gives symptoms than duodenal, and jejunal diverticula are rarely disclosed on roentgenographic examination mainly because retention is absent.

ETIOLOGY

The causes of duodenal diverticula are not well understood. The condition is seldom

seen early in life it usually occurs in the fifth sixth or seventh decade. Various authors have discussed the etiology and among the theories which have been mentioned are herniation of the mucous membrane through a place of lowered resistance in the duodenal wall. This place of lowered resistance, it has been alleged most frequently is due to the penetration of small vessels through the muscular layer. A less often mentioned possible cause of weakness of the wall is the presence of pancreatic tissue at such an area or the presence of fat in the muscularis. Another often expressed theory regarding the formation of these diverticula is that they are caused by outpouching of the duodenal wall similar to the anlage from which developed the liver and the pancreas. Other causes which have been cited are traction either of the pancreatic or common duct or from the head of the pancreas itself when it has undergone focal or widespread atrophic changes due to chronic interstitial pancreatic disturbances. These theories seem to us less tenable than the theory that herniation occurs at a weak spot caused by penetration of the vessels. To substantiate the latter idea is the fact that practically all the diverticula occur on the side of the duodenum or jejunum where the arteries enter and seemingly never on the other border. In the 2 cases we report herein the jejunal diverticula which were large and numerous (Fig 2) were on the mesenteric side and in reality were outpouchings of the mucous membrane between the serosal coverings of the mesentery. The diverticula in this instance were alternately a little to one side and then the other of the line of attachment of the mesentery. Careful examination of jejunal mesenteric attachments demonstrate that the vessels alternate irregularly first on one side and then on the other of the central line of attachment to the mesentery.

Diverticula of the first portion of the duodenum may occur on the superior arch of the duodenum. In the 1 case which we have seen of the diverticulum of the first portion of the duodenum the diverticulum was a true diverticulum whose walls consisted of all coats of the intestine (Fig 3). It is probable that genuine diverticula in this area while more rare

streptomycin if warranted by the clinical and laboratory findings.

17 The percentage of satisfactory results is highest when the requirements of (1) free flow of urine, (2) susceptible organisms, and (3) adequate dosage of the drug are met. (4) Due consideration is given to the management of the patient as a whole.

Fig 1. Roentgenograms showing duodenal diverticula (Case 1). a and b, Preoperative roentgenograms show a large cascade diverticula of the third portion of the duodenum. At operation these proved to be the right and left of the superior mesenteric vessels. They were excised. There are also a diverticula in the descending portion of the duodenum. A retroduodenal diverticulum was inverted at

than in the second and third and fourth portions of the duodenum are always true diverticula and they are congenital in origin. They possibly represent the anlage of pyloric coeca—pouches which occur in certain species of fish and which empty into the duodenum (Kyle). Perhaps this explains why all genuine diverticula in this position are true diverticula. In this presentation we absolutely exclude any consideration of pseudo diverticula caused by scarring of an ulcer.

SYMPTOMATOLOGY

There are no characteristic symptoms of duodenal diverticula to substantiate, with any degree of certainty a presumptive diagnosis of such a condition. Undoubtedly many of the diverticula of the duodenum remain asymptomatic. If one were to base the percentage on autopsy findings probably duodenal diverticula would be asymptomatic in 85 to 90 per cent of cases. However in a series of duodenal diverticula diagnosed roentgenographically probably the incidence of asymptomatic ones is only 25 per cent. This rough guess is based on surmises from reports in the literature and has not been substantiated by actual clinical

operation. c, Postoperative roentgenogram shows that a diverticula in the descending portion of the duodenum persist and were missed at operation. These were probably in the pancreatic parenchyma. At the time that this operation was carried out we were not using air insufflation of the duodenum in order to disclose the location of the diverticula present.

count. Five of 6 diverticula reported by Costello were responsible for symptoms. Spriggs and Marxer estimate that in 47 per cent of their cases the diverticula were responsible for the symptoms.

The most common symptom produced by these lesions is pain. This apparently occurs in about 80 to 85 per cent of the symptomatic cases. The pain is usually dull, it is mild to extremely severe. It may be a mere discomfort or an excruciating agony. It may last minutes to several hours. It occurs in the right subcostal region but much lower than gall bladder pain. In reality it is located in the right lower portion of the epigastric region away from the costal region and just above and to the right of the umbilicus. This pain may radiate through to the back or at times rarely to the right scapula. It is questionable whether the pain of duodenal diverticulum itself ever radiates to the scapula, since in cases in which this has been noted cholecystitis was an associated finding. The time of occurrence of pain is irregular. It apparently is associated with meals but not in a definite time pattern. Experience questioning patients regarding the occurrence of pain after

Fig. 1. Segment of the jejunum removed at operation (Case 5). It is 12 inches in length and contains 7 large and many smaller diverticula. These are false diverticula, thin walled, and consist of mucosa covered by peritoneum. As is usually the case these diverticula protrude through fenestra in the muscularis. They are commonly found on the mesenteric side of the site of entrance of the vessels.

meals left us with no definite idea of a pattern. Apparently it may come soon after a meal or hours after a meal. It may occur on consecutive days and then not occur for weeks. Apparently the pain is due to filling and failure of adequate emptying of the diverticulum. In 1 of our patients pain had the periodicity of a peptic ulcer but the patient did have peptic ulcer in addition to the large diverticulum. Associated with this pain objectively is tenderness. In 1 of our patients in whom pain was a very pronounced symptom the tenderness was striking in the right lower portion of the epigastric region and this was consistent. In the presence of pain there was always tenderness. There was no tenderness directly under the subcostal margin. The second symptom of importance and frequency in these patients is nausea. This is often recorded in the case reports in the literature. In 1 of our patients this alone was the presenting symptom. The patient stated that she has been nauseated for some 12 years. The time of occurrence of nausea was irregular but it had become more frequent in time and duration so that in recent years it occurred daily. She had sought medical aid on numerous occasions and from various physicians but until we studied her the results of examinations had been negative so that the diagnoses previously made had varied between functional gastrointestinal disturbance and neurasthenia. The nausea may be very severe. It may be accompanied by vomiting but this is rare. Nausea may occur at the height of pain but it may occur separately and without pain. This is understood

better if one subscribes to the very probable theory that nausea in reality originates in the duodenum and not in the stomach. Distension of the duodenum or diverticulum of the duodenum is the cause of nausea though the full diverticulum resting on the duodenum may cause partial obstruction and in that manner produce nausea. The third symptom of importance is diarrhea. This occurs far more commonly than one would expect. It is noted frequently in the case reports in the literature. It was a prominent feature in 1 of our patients. Apparently the diarrhea is caused by a pancreatic disturbance. It consists of 4 to 6 loose stools a day extending over a period of a few days. One author (Fulde) has written on chronic disturbance of the pancreas due to duodenal diverticula. In his cases in which he described disturbed pancreatic function diarrhea and a high fat content in the stools were prominent features. Apparently the pancreatic duct may be obstructed partially without obstruction of the common bile duct. Both acute hemorrhagic pancreatitis and jaundice have been described as resulting from duodenal diverticula but that degree of severity of pancreatic disturbance is very rare.

Various other symptoms have been mentioned in the case reports of duodenal diverticula including pain in the posterior lumbar region, sensation of fullness after eating, symptoms simulating cholelithiasis and those simulating peptic ulcer of the duodenum. Weight loss is an imposing feature of certain case reports, the patients having lost 20 to 30 pounds.

Fig. 3. Roentgenograms showing a huge diverticulum of the first portion of the duodenum in a young man exhibiting symptoms simulating peptic ulcer (Case 4). This is a genuine, true diverticulum, and one whose walls are made up of all the coats of the duodenum. This may be equivalent to

the pyloric cecum of fish. In this case a gastrectomy was done. a and b The preoperative roentgenographic appearance of the diverticulum immediately after the ingestion of barium. c, Residual pooling of barium in the diverticulum 6 hours after the ingestion of barium.

The symptoms of duodenal diverticula may continue and usually do over a period of many years without the diagnosis being made. Indeed the diagnosis is rarely suspected merely from the subjective complaints of the patient because whatever symptoms a duodenal diverticulum causes may be attributable to the other conditions.

COMPLICATIONS

Complications of duodenal diverticula are not common but the most bizarre complications do occur. Acute diverticulitis has been reported with the severe symptoms of an acute abdomen. Recovery of patients following surgical removal of acutely perforated duodenal diverticula has been reported by Huddy, Lucman, Monsarrat. Acute perforation results in the symptoms of severe acute abdominal catastrophe. Boland (1936) has done the profession a service to call attention to the fact that an acutely inflamed diverticulum which has caused peritonitis can be overlooked unless the surgeon is cognizant of this possibility. He operated upon a patient and it was recognized that the man had peritonitis but no definite origin of the condition could be ascertained at

operation. The patient died and at necropsy an acutely perforated duodenal diverticulum was found to explain the process. If the knowledge of this possibility is realized by the surgeon when there is an otherwise undisclosed cause of peritonitis the surgeon will not fail to seek this explanation and thus possibly save his patient. Beaver reported a similar case. Melchior described phlegmonous duodenitis resulting from diverticulitis. Hemorrhage is another rare but apparently authentic complication of diverticula of the duodenum.

Obstructive jaundice is another complication which though rare may be due to either pressure by the diverticulum or to an enterolith in the diverticulum as in the case reported by Nicholson. Harris and Watson and Terry and Mugler have reported stones in diverticula. Another complication which seems to be extremely rare is carcinoma occurring in the diverticulum. Strode has reported 1 such case. The patient operated upon with removal of duodenum and head of pancreas and recovered.

DIAGNOSIS

There are two ways in which the diagnosis may be made. It may be confirmed after it is

Fig. 4. Representation of a diverticulum of the descending portion of the duodenum protruding into the pancreas. a, Before, and, b, after incision of the duodenum with air. After the duodenum is pumped up with air the head

of the pancreas bulges disclosing the position of the diverticulum. Diverticula of the descending portion of duodenum have often been missed at operation. This is an added technical help in disclosing their position at operation.

suspected by a very astute clinician who has various investigations made such as cholecystograms and a roentgenographic search for duodenal ulcers with instructions to the roentgenologist to make a careful examination for duodenal diverticulum or the diagnosis may be stumbled upon without its possibility having been considered by the clinician and with it becoming manifest only as it were accidentally during a gastrointestinal roentgenographic study which was made with the thought that peptic ulcer may be causing the symptoms. Obviously it is more gratifying to have considered the correct diagnosis and have it disclosed by roentgenography. Instructions to the roentgenologist that duodenal diverticulum is a possibility will undoubtedly result in disclosure of this lesion in a higher percentage of cases.

The diagnosis of duodenal diverticulum is not easy even though the diverticulum be sufficiently large to cause the symptoms for which the patient sought relief. Almost any type of upper gastrointestinal complaint from mild to severe may be attributable to duodenal diverticulum. The thought of this possibility makes the diagnosis easier. Subjectively there is nothing characteristic about the symptoms to lead one to the correct diagnosis and even a presumptive diagnosis is not justified on subjective evidence. Objectively tenderness in the right lower portion of the epigastrium is a suggestive but not a conclusive finding. The real diagnosis of duodenal diverticulum depends upon its roentgenograph

ic exposure. Then and only then is one justified in making the diagnosis with any degree of assurance. When the diagnosis has been made there is still the problem of evaluating the relationship of the diverticulum to the symptoms. The mere fact that a diverticulum is proved to be present in a duodenum does not assure one that it alone is responsible for symptoms. For that reason whenever this diagnosis is being established it is important to have a cholecystogram and roentgenographic studies of the gastrointestinal tract. Then careful consideration of the subjective and objective findings in the case may lead one to a true evaluation of the part a duodenal diverticulum is playing. Residual pooling of the barium in the diverticulum would seem to be a very important feature upon which to base judgment as to whether the symptoms are largely due to the diverticulum itself.

JEJUNAL DIVERTICULA

Diverticula are found in the jejunum more rarely than in any part of the gastrointestinal tract. Fraser indicated the frequency of diverticula in the various parts of the gastrointestinal tract as follows: first colon, second ileum (Meckel's diverticulum), third duodenum, fourth pharynx and esophagus, fifth stomach, sixth jejunum. When diverticula occur in the jejunum they are most frequent near the ligament of Treitz and diminish distally in size and number. They are most often multiple and are found in numbers from a few to hundreds in any given cases. They practi-

Fig. 5. Diverticulum of the descending portion of the duodenum which has presented posterior to the duodenum before and after mobilization of the duodenum. Diverticula of the descending portion usually occur around the ampulla of Vater and usually the fundus is located posteriorly to the duodenum itself necessitating an incision in

the peritoneum lateral to the duodenum on the right with elevation of the duodenum and the pancreatic head. b, The duodenum here is represented as being turned to the left. A hemostat is placed across the base of the diverticulum prior to its excision. The fenestrum in the muscularis is then closed with interrupted silk stitches.

cally always occur as false diverticula, that is as herniations of the mucous membrane through the muscular coat of the intestinal wall. The diverticula protrude through fenestra between the leaves of the attachment of the mesentery at the point of emergence of arteries. They may be huge. One as large as an apple and 6 as large as billiard balls were reported in 1 case by William Osler

The extreme infrequency of these lesions is illustrated by such facts as those reported by Rosedale viz. 3 instances of diverticulosis of the jejunum in 5 000 autopsies and Edwards 9 cases of diverticula of the jejunum in 2,820 autopsies an incidence of 0.3 per cent. Radiographic disclosure of jejunal diverticula during life is even more rare. Rankin reported that in 72 715 gastrointestinal examinations of the stomach and duodenum 111 duodenal diverticula were found (0.15%) and in 956 studies or serial x ray examinations of the small bowel only 3 instances of jejunal diverticula were found. The cases of diverticula of the jejunum and ileum at the Mayo Clinic up to 1932 total 52 3 found roentgenographically, 18 discovered at operation and 31 at necropsy. These did not include Meckel's diverticulum nor diverticula of the duodenum. Thirty-eight were males. Thirty had symptoms relative to the gastrointestinal tract. Forty-one had diverticula of the jejunum 13 of the ileum. At no time did a patient go to surgery for relief of symptoms thought to be due to the diverticulum

Jejunal diverticula cause symptoms in a much smaller percentage of cases than duodenal diverticula of comparable size. The reason being that the duodenum is fixed and the jejunum relatively free and motile constantly changes the position of the ostia of the diverticula so that emptying is facilitated. Pain, borborygmi and flatulency have been cited by numerous authors as the usual symptoms of jejunal diverticula. William Osler described a case in which a patient avoided his companions immediately after meals because of the loud noises which resulted from filling and emptying of the diverticula. Pain may be very severe and crampy. Diverticulitis of jejunal diverticula though rare has been reported by Ovens and others. Actual perforation also occurs according to Shutkin. Enteroliths occurring in a jejunal diverticulum may cause obstruction as reported by Watson and Terry and Mugler. Obstruction resulting from adhesions to jejunal diverticula has been reported by Hubeny and Pollack.

Apparently in the past even when the gastrointestinal symptoms are present surgeons and clinicians have been unwilling to attribute them to diverticula of the jejunum disclosed either at operation or by roentgenographic examination. Perhaps this incredulity has been partially due to a sensation of danger attached to the removal of these diverticula or to resection of the jejunum. Now that surgery of this part of the alimentary tract has been made relatively safe by numerous advances in re-

Fig. 6 Diverticula of the third portion of the duodenum usually arise from the superior concave surface. These may be approached through the transverse mesocolon by an incision into its superior layer *a*, or if they are further to the left of the superior mesenteric vessels they may be approached through the transverse mesocolon from below as represented in *b*. These diverticula may be easily excised or inverted and the fenestrum in the muscular layer closed with interrupted silk stitches. The peritoneum is carefully closed over this.

cent years, the indications for direct attack on these lesions must be broadened and undoubtedly when more such lesions are commonly alleviated by capable surgeons who then report their good results it will be more readily accepted that prompt removal of them is indicated when they produce troublesome symptoms.

TREATMENT

The treatment of diverticula of the duodenum and jejunum depends on whether they are causing symptoms or not. Presumably their disclosure by roentgenographic examination is always in a patient who has some gastrointestinal symptoms. Even when diverticula are known to be present it sometimes though not usually may be justifiably concluded that they are not the cause of the patient's symptoms. For example cholelithiasis may also have been demonstrated when the symptomatology is typical of cholecystitis and cholelithiasis. In such instances judgment as to whether the diverticulum should be removed is secondary to judgment on the indications for treatment for cholelithiasis. Usually both lesions should be removed simultaneously.

When it is concluded that the diverticula are causing symptoms the question of treatment cannot be divided into medical or surgical. It can only be decided on the basis of whether surgery can justifiably be denied the patient because of the gravity of his symp-

toms or justifiably offered him because of the minor nature of his complaints. In reality there is little medical treatment. Among measures which have been suggested are bland diet, mineral oil and lateral recumbency on one side or another after each meal. Acceptance of this management is justified only for patients whose physical condition precludes operation. Otherwise surgery is indicated if the symptoms are severe enough. Complete relief by surgery can be expected with an extremely low risk to the patient. In the past too little appreciation and experience with the effects of these diverticula have left surgeon and clinician without appraisal of the results of surgery. For that reason clinicians have hesitated to recommend removal by the surgeon and the surgeon perhaps himself did not realize what tremendous relief he could give his patient by removing the diverticula. Perhaps the fact that today the risk has been greatly diminished over that of even 10 years ago justified a more radical attitude toward these lesions either when they are disclosed by roentgenographic examination or found incidentally at the operating table.

TECHNICAL FEATURES OF THE OPERATION

Removal of the diverticulum appeals to us as the most desirable operation provided other factors permit this to be done without unjustifiably increasing the risk to the patient. Location of the diverticulum at operation is not al-

Fig. 7 Roentgenograms showing a diverticulum of the descending portion of the duodenum arising near the ampulla of Vater (Case 3). In a the position of the diverticulum has been indicated by surrounding it with white lines. The diverticulum is partially filled. b, Six hours after ingestion of the barium meal the diverticulum still retains

part of the barium. This patient had severe attacks of pain preoperatively. She has been completely relieved of all symptoms for a period now of 18 months following the operation. c, Postoperative roentgenogram disclosing no evidence of the diverticulum which was excised at operation.

ways easily accomplished. As has been indicated above these diverticula have been missed in a high percentage of the patients operated upon and even by extremely able surgeons. The diverticulum itself extending posteriorly may be entirely covered by the duodenum or protrude to the right of the duodenum. Others occur in the head of the pancreas and when collapsed in the prepared patient who has been fasting and at the operating table they may not show. For this reason we have devised the following means of demonstrating the position of the diverticulum. A 20 cubic centimeter syringe carrying a 22 gauge needle is used. The needle is inserted into the duodenum and the duodenum is pumped up with air. Thirty to 40 cubic centimeters of air is necessary. When the duodenum is ballooned out the diverticula may be disclosed even if they are in the head of the pancreas and entirely covered by parenchyma (Fig. 4). Under the circumstance of air insufflation the head of the pancreas expands so that a diverticulum therein may be discovered. This also shows diverticula in the third and fourth portions of the duodenum in the leaves of the transverse mesocolon. After the

lateral peritoneal attachment of the duodenum is severed and the duodenum is turned partially forward any posterior diverticulum may be disclosed (Fig. 5). The diverticulum is then carefully dissected from surrounding structures and the neck severed between two clamps. The edges of the mucosa which have been agglutinated by the pressure of the clamp are inverted using chromic No. 00 catgut suture. The muscular defect and the serosal layers are closed with interrupted silk stitches. Diverticula in the region of the ligament of Treitz may be difficult to disclose. We have severed the inferior fold of peritoneum on the transverse mesocolon to approach these (Fig. 6) and by pumping up the duodenum they may be found and excised. Diverticula of the third portion of the duodenum to the right of the mesenteric vessels may be approached through the superior leaf of the transverse mesocolon.

A diverticulum protruding into the head of the pancreas may be very difficult to remove but merely because of position removal is not impossible. Separation of the pancreatic parenchyma from the diverticulum may be achieved by careful dissection. We did this in

Fig. 8. Jejunal diverticula shown roentgenographically in various phases. Arrows indicate the position of the diverticula.

In this instance (Case 6) a segment of jejunum containing a large and several smaller diverticula was resected.

1 of our cases in which the diverticulum was quite large and in which it was necessary to remove pancreatic parenchyma from the entire sac. The technical feature advocated by Maclean of opening the duodenum and inserting the finger into the diverticulum may facilitate removal of a diverticulum so located. We have not employed this method. Ferguson and Cameron advocated giving the patient a mixture of barium on the evening before or morning of the operation to facilitate disclosure of the lesion at operation. The barium coats the diverticulum and makes it appear white.

Inversion of the diverticulum after the sac is entirely separated from the surrounding structures is easily accomplished. This maneuver is very tempting because it offers a certain amount of security against leakage and contamination but somehow it is not as appealing as complete removal of the diverticulum. When the diverticulum is closely associated with the common bile duct and when its removal and necessarily tight closure may compromise the patency of the duct or when other technical features would make removal an increased risk, inverting the diverticulum may be the best choice. We have inverted several in our cases some of which we feel today we would remove in preference. Barnes is to be credited with the assertion that inversion may be followed by enlargement of the

mucous membrane with the accumulation of a gelatinous material inside the inverted diverticulum and that this ultimately may lead to obstruction. His authority for this is difficult to find since he does not report this as having occurred in his cases and since he does not quote specifically another author to substantiate the statement. Nevertheless, the larger diverticula if inverted might cause partial obstruction or interference with the intestinal flow. Because of the lack of peritoneal covering on the posterior and pancreatic surfaces of the duodenum the diverticula arising there, if not too large, may be inverted as additional safety to prevent leakage since there is absence of serosal covering. Diverticula of the terminal portion of the duodenum may easily be excised, the mucosa sutured over with catgut and interrupted silk stitches employed to close the muscular and serosal layers.

Diverticula of the first portion of the duodenum may easily be excised even though they are true diverticula. If there is an occasion for excision of a segment of the stomach as there might well be when there is a stenosing ulcer excision of the diverticulum at the same time is a procedure of choice.

Numerous operations have been advocated and done for duodenal diverticula. It is obvious to most authors that excision is a most desirable procedure but fear of excision has led many to choose other less effective operations.

operations done in the past have been enterostomy gastroenterostomy with division of the duodenum and excision of the diverticulum inversion of the diverticulum permitting it to run enteroenterostomy to short circuit the contents around the jejunal diverticulum, excision of the duodenum and head of the pancreas (for carcinoma in the diverticulum). Jejunal diverticula are less frequently operated upon. Since they are usually multiple and since their ostia are sometimes exceeding large excision of a long segment of jejunum may be the best procedure. Dissection and removal of each diverticulum might entail a very tedious procedure with more element of danger from leaks at numerous places. If there is one large diverticulum excision is advisable or if it is extremely large with a wide base, resection of this jejunal segment with anastomosis is indicated.

CASE REPORTS

The following are brief case reports of 6 cases of duodenal and jejunal diverticula. Four of these patients had duodenal diverticula and 3 had jejunal diverticula. All of these patients had symptoms. Five of them had symptoms from the diverticulum and in each instance operation relieved them of these symptoms. The sixth patient had a gastric ulcer and at operation giant diverticula of the jejunum were discovered. It was feared that if the jejunum was anastomosed to the stomach with these giant diverticula opposite the stomach, the fixation thus of the jejunum would result in symptoms of stasis or obstruction. It is possible that these diverticula were already giving symptoms but if they were the symptoms were overshadowed by those of the severe gastric ulcer.

CASE 1. E.R.S. a white female aged 61 years, gave a history of epigastric pain and discomfort for the preceding 2 years. These symptoms were very severe at times, and there was no definite relation to eating. During the year before admission to the hospital her symptoms became worse and she lost 15 pounds in weight. Objectively there were few findings of significance. There was slight tenderness in the epigastrium. Roentgenographic examination with a contrast meal revealed diverticula of the duodenum, 3 of them being quite large (Fig. 1) After

observation here she returned to her home in a distant city but the pain became very severe and she decided to return for an operation which had been offered her with the prospect of relief but had not been urged upon her.

At operation the peritoneum was cut on the right lateral border of the duodenum and the duodenum was mobilized and turned toward the left to expose its posterior surface. There a large diverticulum was exposed (Fig. 5). The sac was remarkably thin and consisted only of herniated mucosa. It had the same diameter as the bowel. Near the medial border in the region of the ampulla of Vater was a large oval fenestration in the muscular layer. The os was quite large. The diverticulum was inverted into the lumen of the duodenum and the margins of the fenestrum of the diverticulum with interrupted silk sutures. The third and fourth portions of the duodenum were approached through the inferior surface of the transverse mesocolon. Arising from the superior concave portion of the third part of the duodenum were 2 large diverticula each 3 centimeters in diameter. One was found on each side of the superior mesenteric vessels. Each of these was excised. The mucosa was closed with fine catgut and the fenestra in the muscularis through which these had herniated were closed with interrupted silk stitches.

At this time we were not using air insufflation to disclose diverticula. Postoperative roentgenographic studies revealed that we had missed a diverticula of the descending portion of the duodenum (Fig. 1). Apparently the retroduodenal one inverted at operation did not show on preoperative examination. Those which were missed may have protruded into the head of the pancreas. These fortunately were not the largest diverticula and may have been asymptomatic since 1 year after operation this patient reported that she was free of gastrointestinal symptoms. Unfortunately however she was left with a tragic residual of the operation. This operation was done soon after the advent of "continuous spinal" anesthesia. Permanent nerve damage to the cauda resulted in bladder residual and slight rectal incontinence.

CASE 2. J.W.T. a white female aged 27 years complained of intermittent upper abdominal pain which had been occurring for some 3 years and was increasingly more severe. The pain was always in the same place to the right of the midline and low in the epigastrium or just above and to the right of the umbilicus. A nauseated feeling had often been present with or without the presence of the pain. This sensation and the pain were both initiated or increased by eating. It was almost always present in recent months. At times the pain was most severe. It was dull and did not radiate but during some attacks it did require opiates for relief. Objectively the only significant finding in the entire physical examination was definite tenderness in the right lower epigastric region. It was variable in severity but when she had nausea or pain tenderness was always present. Roentgenographic examination

disclosed a large diverticulum arising from the descending portion of the duodenum.

The diverticulum was found at operation arising from the posterior surface at the midportion of the descending segment of the duodenum. In order to approach the diverticulum the duodenum was mobilized and turned to the left. The common bile duct was found to enter the duodenum at the base of the diverticulum. The diverticulum was excised with care not to injure the common duct. The fenestration in the muscular coat was closed with chromic No. 00 catgut and a double row of investing fine silk sutures. The postoperative course was uneventful. Since operation 15 months ago this patient has had complete relief of her symptoms. Postoperative roentgenographic examination failed to reveal any evidence of the diverticulum (Fig. 8).

CASE 3. H.M.H. a white female, aged 51 years, had constant nausea for the past 12 years. The patient had been treated elsewhere for years with diets but no relief was experienced. This patient had no symptom other than nausea. The nausea was very severe. She said she was always nauseated. Various examinations had been made by numerous doctors with always essentially the same conclusions, either functional gastrointestinal complaint or neurasthenia. Objectively nothing significant was found on physical examination. So one was tempted to agree with previous diagnoses. We felt that roentgenographic examination of the stomach should be repeated and that it should be done extremely thoroughly and by a most expert roentgenologist. After all the diagnosis depended entirely on his findings. This examination revealed a diverticulum 1.5 centimeters in diameter arising from the second portion of the duodenum and a second large diverticulum 3 centimeters in diameter near the ligament of Treitz. At 4 hours these diverticula remained filled with barium and shadows were noted suggesting probably another large and a small diverticulum in the jejunum.

At the operation a large diverticulum near the ligament of Treitz was excised and the stump inverted with No. 00 chromic catgut and interrupted fine silk sutures. Two smaller diverticula in the jejunum were inverted with interrupted silk sutures. Air was then injected into the duodenum by means of a needle and syringe (Fig. 4). This procedure helped to locate the diverticulum in the second portion of the duodenum. It originated from the pancreatic surface and extended into the head of the pancreas to the left of the duodenum. Without the aid of air injection this diverticulum would not have been found. The diverticulum was carefully dissected free from the pancreas and was inverted into the duodenum with interrupted fine silk sutures. Because its origin was so intimately associated with the ampulla of Vater it was felt that this was a safety measure and permissible since the diverticulum was not huge. The gall bladder was also removed because it was large and redundant. In the convalescence the patient had a subhepatic

infection with resulting drainage for several weeks. Since operation, she has been entirely free of nausea for the first time in 12 years. She has gained weight, looks entirely well, eats her meals with pleasure and in every way has had a most gratifying result from her standpoint and from the standpoint of surgery.

We have no way of knowing whether her diverticula were discovered at previous examination and discounted as not being accountable for the symptoms or whether due to inadequate roentgenographic studies, they were not then disclosed. With the generally existing attitude regarding duodenal diverticula either alternative may have been the cause of her failure to get into the hands of an able surgeon for 12 years.

CASE 4. C.McC. For over 14 years the patient, a man, aged 30 years, had been having recurrent gastric hemorrhages and postprandial epigastric pain occurring periodically with long periods of remission. He had had an operation (gastroenterostomy) 14 years ago which did not definitely affect the symptomatology. Most of the hemorrhages had manifested themselves as melena and had recurred many times. Two weeks previously dark bloody stools showed again. Pain had become more severe recently and was diffusely distributed all over the abdomen. Ucer diet and antacids had not given the patient relief in this attack. The physical examination revealed little of note. The blood pressure was 115 millimeters of mercury systolic, 68 diastolic. Gastrointestinal roentgenographic series showed a gastroenterostomy with functioning stoma. A large diverticulum as found in the concavity between the first and second portions of the duodenum (Fig. 9). This diverticulum was the size of a satsuma, measuring 7 centimeters in transverse diameter. Six hour observations show retention of barium in the duodenal diverticulum.

Operation was performed December 20, 1946. A large diverticulum was found under the first portion of the duodenum. It was a true diverticulum with walls comprised of all layers of normal duodenum and it was a genuine not a pseudodiverticulum, i.e., it was not due to cicatricial contraction of an ulcer. A small stellate scar was noted on the anterior aspect of the duodenum just proximal to the diverticulum but there was no contraction nor stenosis of the duodenum. The first portion of the duodenum and the distal 45 per cent of the stomach was resected leaving the anterior gastroenterostomy intact. Usually we remove about 60 per cent of the stomach when doing a gastrectomy and this "limited" resection was performed to obviate the necessity of disconnecting a satisfactory gastroenterostomy stoma. The stoma was carefully inspected and seemed to be entirely free of disease. The end of the stomach was closed. Then after severing the peritoneum around

AMINO ACIDS AND HYDROLYZED PROTEIN

PROTEIN deficiencies in the surgical patient are now recognized as of great clinical importance. Because of this, a variety of methods has been developed for the administration of protein in addition to the usual normal method by which protein is ingested in the food. For example, the therapeutic value of blood transfusions resides largely in their protein content which of course occurs in at least two forms (1) as hemoglobin within the red blood cells and (2) as the various plasma protein fractions, particularly albumin. Plasma albumin, because of its large molecular size, exerts an important function in holding fluid within the capillary lumen, and substitutes for it must possess a similar colloidal property. Transfusions of blood and plasma are primarily useful for the immediate prevention or correction of acute deficits following loss of blood or plasma in a variety of surgical patients.

Protein deficiency of nutritional origin presents a different problem. This type of deficiency primarily follows protein deprivation in the diet, and is aggravated by any condition which produces an increased loss of protein tissue. When these patients are unable to ingest and assimilate protein by mouth, correction or prevention of protein deficiency is found to be impossible unless there is some method available for the introduction of this essential element through the parenteral channel.

Under normal conditions protein is utilized only after digestion during which process the large protein molecules are broken down into smaller building stones, including both the amino acids and small combinations of them usually called peptides. After absorption into the blood stream, these amino acids and peptides are carried throughout the body to be manufactured into tissue proteins, i.e., proteins, hormones, enzymes, etc., each of which has its own characteristic amino acid composition. Should the parenteral channel be required it seems clear that a similar process should be devised. Normal protein nutrition can be maintained only by the utilization of an appropriate mixture of amino acids, whether it originates from food protein or from protein digests supplied as such either by mouth or by injection.

Amino acid mixtures are available for intravenous injection and they are widely employed therapeutically to supply parenteral protein food. Strictly speaking, the amino acid mixtures should be limited to the pure crystals dissolved in water; this method is impractical at the present time because of its cost. Similar mixtures as now used may o

the esophagus the esophagus was pulled down and the diaphragm pushed up and 3 to 4 centimeters of the vagus nerves were removed.

Examination 2 months after operation finds him entirely well except for slight fullness after eating a large meal.

CASE 5. G.B.G. a white male aged 64 years, had had attacks of indigestion for 25 years. For 3 months he had suffered rather severe almost continuous epigastric pain. He had had pain which was severe and which occurred soon after meals and lasted for several hours. It was not relieved by food. He also had several episodes of melena and hematemesis during this time. Roentgenographic examination with a contrast meal revealed a large ulcer crater on the lesser curvature side of the antrum about 2 centimeters above the pylorus. The roentgenologist stated that the ulcer had penetrated into the pancreas. Gastric retention of approximately 10 per cent was noted at the end of 6 hours.

At operation in addition to large gastric ulcer that had perforated into the pancreas there were 12 large diverticula in the first 12 to 18 inches of the jejunum (Fig 3). All of the diverticula were on the mesenteric side. Some of the diverticula were larger in diameter than the jejunum itself. A gastric resection was performed and a section of the jejunum 12 inches in length containing most of the diverticula and all of the large ones were removed. An end-to-end anastomosis of the jejunum was accomplished. A Hofmeister type of reconstruction completed the procedure. The postoperative course was uneventful. At follow up 1 year later the patient reports that he is completely well.

CASE 6. J.H., a man, aged 44 years, had symptoms relating to his present illness for only 2 months. He complained of pains in the upper abdomen more severe in the epigastrium but radiating from the right lower quadrant or the left upper quadrant of the abdomen to the epigastrium. These pains were extremely severe. They were sporadic and transient but they bothered him a great deal so that he was willing to have anything done which would insure him relief.

Objective examination revealed very little of significance merely slight tenderness in the epigastrium. The real diagnosis was made by means of x ray Roentgenographic gastrointestinal studies showed two large diverticula in the jejunum.

At operation 16 centimeters below the ligament of Treitz was a large diverticulum, a herniation of the mucosa on the mesenteric border. Another diverticulum was found 8 centimeters farther down the bowel. This one was 5 to 6 centimeters in diameter in the distended state. The fenestra in the muscularis which permitted these mucosal hernias were large and for that reason to remove the diverticula a segment of the jejunum containing both diverticula was resected. An aseptic end-to-end anastomosis was accomplished. The patient had an uneventful convalescence. He recovered and has been entirely relieved of his symptoms.

SUMMARY

Diverticula of the duodenum are by no means rare occurring in from 1 to 2 per cent of all patients who have roentgenographic studies made for gastrointestinal symptoms. Up until now the generally prevailing opinion in the profession is that these lesions are relatively innocuous and rarely, even though present cause symptoms. Such is not the case. They frequently are responsible for symptoms of a very troublesome and sometimes of a very disabling character. Surgical operation to obviate the presence of these diverticula either by inversion into the intestinal canal or by actual removal cures the patient. The indications for operation are discussed and when duodenal diverticula large enough to cause residual pooling of barium are present, removal or inversion is indicated even though the patient is operated on primarily for a coexisting lesion such as cholelithiasis, and though removal of the gall bladder is accomplished at the same time.

We have discussed the location, the etiology, the symptomatology, and diagnosis of these lesions.

Jejunal diverticula are much less common than diverticula of the duodenum and much more difficult to diagnose preoperatively. They may cause severe symptoms and surgical removal of them results in cure. They should not be regarded merely as incidental findings, an opinion which has been frequently expressed in the past. They probably warrant operation in a high percentage of cases in which they are diagnosed.

We have discussed the technical approach to diverticula of the duodenum and jejunum. In the past judging from reported cases these diverticula have frequently been missed at operation. We have described a new technical procedure of pumping up the duodenum with air to show diverticula which may be hidden particularly those protruding into the head of the pancreas or into the retroduodenal area. This new procedure should insure their discovery at the operating table and thus facilitate their removal.

A group of 6 cases 4 of diverticula of the duodenum and 2 of diverticula of the jejunum were reported by us. In all of these cases

operation was carried out and each patient was relieved of his symptoms.

CARCINOMA OF THE LARYNX

Methods and Results of Treatment

GORDON B NEW M.D. F.A.C.S. FREDERICK A FIGI M.D., F.A.C.S.

FRED Z HAVENS M.D. F.A.C.S., and JOHN B ERICH M.D. F.A.C.S., Rochester Minnesota

IN recent years, the frequency and seriousness of carcinoma of the larynx have become generally recognized and physicians have developed an increasing interest in the treatment of this disease. As a matter of fact, the therapeutic measures designed to cure this condition have become sufficiently diversified to arouse genuine controversies in regard to policies of treatment. It is our opinion that no one method is superior to all others; on the contrary, the type of treatment to be instituted in any given case must be governed by the type and extent of the growth which is present. In support of this opinion we wish to present the methods of treating carcinoma of the larynx at the Mayo Clinic and the end results of such management. This presentation is based on a study of 568 patients who were treated for malignant laryngeal neoplasms at the clinic during a 10 year period 1934 to 1943 inclusive (Fig 1).

At the clinic, every patient with symptoms referable to the larynx is required to give a thorough history of his symptoms. Roentgenograms of the thorax, studies of the blood, urinalysis, serologic tests for syphilis and examination of the sputum if indicated are made and a general physical examination is performed. The larynx itself is examined by the indirect method and in many instances roentgenograms and tomographs of the larynx are obtained.

When on indirect laryngoscopy a lesion of the larynx is found to be fungating or ulcerated, to cause fixation of a vocal cord or to produce a metastatic mass in the neck, there can be little question concerning the nature of the neoplasm. However on mere visual inspection many malignant laryngeal tumors cannot be distinguished from certain benign growths, tuberculomas, or syphilomas. For

instance, early laryngeal epitheliomas of a projecting papillary character that have not infiltrated deeply enough to cause fixation of the vocal cord may be confused with benign papillomas. Papillary inflammatory growths often are more difficult to distinguish from papillary carcinomas than are papillomas. Occasionally an early infiltrative carcinoma without ulceration on a mobile cord can easily simulate one of many types of benign tumor. Distinguishing clinically between papillary leucoplakia or epithelial hyperplasia and papillary epithelioma often is impossible; however such a distinction is unnecessary since thickened leucoplakia and epithelial hyperplasia always should be considered malignant until proved otherwise by microscopic examination.

Because mere visual inspection by indirect laryngoscopy cannot offer an unerring diagnosis it becomes evident that biopsy of every laryngeal tumor is absolutely essential. We believe that removal of a specimen for biopsy is carried out most effectively under suspension laryngoscopy. We use the Lynch suspension apparatus through which an excellent view of the larynx can be obtained; it leaves both hands of the surgeon free to manipulate such instruments as are necessary for obtaining the specimen.

On our hospital service a specimen of tissue from the larynx obtained under suspension laryngoscopy is examined at once by the frozen section method. This enables a competent pathologist to give the surgeon a definite histologic diagnosis usually in a few minutes. An immediate microscopic examination of frozen sections of tissue while the laryngoscope is still in place has two distinct advantages. First, if the pathologist finds that the first specimen of tissue is unsatisfactory for diagnosis, another piece of tissue can be obtained without delay. Second if a laryn-

Fig. 1. Treatment of patients who had malignant laryngeal neoplasms from 1934 to 1943 inclusive.

geal growth is found to be malignant but meets certain specifications that will be discussed later it can be removed or treated without delay.

It seems to us that close co-operation between the pathologist and the laryngeal surgeon is essential in treatment of carcinoma of the larynx. Not only is histologic examination of laryngeal tumors necessary in making an accurate diagnosis, but it is equally important in determining the degree of activity of malignant lesions. At the clinic carcinomas are graded, according to their microscopic appearance from 1 to 4, grade 1 being the least malignant and grade 4 the most malignant (Broders classification). The grade of malignancy is one of the very important factors in selecting the form of therapy most suitable in each individual case of carcinoma of the larynx.

It is our belief that the surgeon who assumes the responsibility of obtaining a specimen for biopsy from a laryngeal tumor should be competent and prepared to treat the lesion. If a specimen of tissue is removed by someone else before the surgeon sees the patient it often is difficult for the surgeon to determine the extent of the lesion. Such a circumstance can jeopardize the patient's chance for a cure by a conservative operation the surgeon not knowing the exact limits of the growth, may find it necessary to perform a more radical surgical procedure than would have otherwise been necessary.

We would like to reaffirm our opinion that accurate diagnosis is essential in the care of malignant laryngeal neoplasms. Accurate diagnosis is based on thorough physical exam-

ination indirect and suspension laryngoscopic examinations and detailed histologic examination of a specimen of the tumor.

TREATMENT

At the clinic four methods are used for treatment of carcinoma of the larynx. They may be listed as follows: (1) thyrotomy (laryngofissure) and surgical removal of the growth; (2) laryngectomy; (3) removal or treatment of the local lesion under suspension laryngoscopy; and (4) external irradiation. The selection of the most suitable method in each individual case of carcinoma of the larynx is based on four factors: (1) size, location, and extent of the laryngeal growth; (2) grade of malignancy; (3) presence or absence of extralaryngeal extensions of the disease or metastasis to the cervical nodes; and (4) age and general physical condition of the patient.

All of these factors must be considered carefully in determining just what type of treatment should be employed in each case. Complete removal of the neoplasm is the prime consideration in any of the operative procedures, but unnecessary sacrifice of the voice should be guarded against. A radical operation should not be employed when a conservative one will remove the neoplasm equally well and will leave the patient with a good functional voice. On the other hand, a conservative operation should not be used when a more radical procedure is indicated as when the neoplasm is highly malignant and has probably extended beyond its apparent limits.

It always is a poor plan to try some conservative form of treatment with the assumption that, if the results are not good, something else can be attempted later on. This is detrimental to the patient's opportunity for a permanent cure as postirradiated cancer of the larynx is difficult to cure even by laryngectomy. It is well to remember that the patient who has a carcinoma of the larynx has but one good chance to get well, and if the first method fails, it is likely that subsequent methods also will fail. Consequently the laryngologist should not use one form of treatment and then another in the hope that one of them will destroy the tumor completely. On the contrary, he should carefully consider in

each individual case all of the four factors previously mentioned and decide which method is most likely to effect a cure

It is more or less generally accepted that low grade malignant tumors are radioresistant and, in consequence are better treated surgically whenever possible. We believe that grade 1 or 2 carcinomas of the larynx which have not metastasized are treated more successfully by operation than by irradiation. Furthermore in our experience most grade 3 laryngeal cancers, if not too extensive, are also more likely to be cured by surgical means. Since about 93 per cent of laryngeal carcinomas are grade 1, 2 or 3 (Table I) it is evident that at the clinic the great majority are treated by surgical measures. It is our opinion that irradiation is the treatment of choice for grade 4 carcinomas of the larynx unless the lesion is small and well localized.

One argument sometimes advanced to discredit the surgical management of malignant lesions of the larynx is the immediate risk (hospital mortality) of such operations. However as is shown in Table II in 446 cases in which operation was performed at the Mayo Clinic from 1934 to 1943 inclusive there were only 8 (1.8 per cent) hospital deaths. Furthermore during the past 7 years due to some refinements in surgical technique and due to the advent of sulfa drugs and penicillin 428 patients were operated on for carcinoma of the larynx with only 2 (0.47 per cent) hospital deaths and both of these deaths were due to coronary thrombosis. Consequently we believe that the hospital mortality associated with surgical management of carcinoma of the larynx need be of no concern.

These hospital mortality rates are low as the direct result of several factors in addition to the two mentioned. Close co-operation between trained surgeons, assistants, and nurses at the time of operation and co-operation between the surgeon and physician anesthesiologists are contributing factors. We believe that the use of cervical block anesthesia rather than general anesthesia contributes to the lowness of our hospital mortality rate in major laryngeal operations (thyrotomies and laryngectomies). It is obvious, of course, that satisfactory block anesthesia can be effected only

by a highly skilled anesthetist. Care given by specially trained assistants and nurses during the postoperative period of hospitalization also is a favorable influence.

THYROTOMY (LARYNGOFISSURE)

No definite rules have been set down for determining which malignant tumors in the larynx can be removed by thyrotomy and which should be treated by laryngectomy. Such a decision requires experience and surgical judgment. However the type of tumor which is ideal for removal by thyrotomy is of a low grade of malignancy and is confined to the anterior two-thirds of a vocal cord which is freely movable. Carcinomas of similar type and location which have infiltrated the tissues of the cord a trifle so as to cause slight fixation of the anterior part of the cord usually still can be removed by thyrotomy provided that the portion of thyroid cartilage adjacent to the growth is removed along with the tumor. Extension of a low grade carcinoma across the commissure does not preclude the possibility of extirpation by thyrotomy. As a matter of

TABLE II.—CARCINOMA OF THE LARYNX 446 PATIENTS OPERATED ON HOSPITAL DEATHS*

Thyrotomy	24	4	
Suspension laryngoscopy	40		—
Total	446	8	1.8

*During the last 7 years 428 patients were operated on; only 2 (0.47 per cent) of these patients died.

fact superficial low grade epitheliomas involving the anterior half of both cords can be removed satisfactorily by thyrotomy the result of such an operative procedure is a rounded opening in the posterior portion of the larynx which offers the patient an adequate airway and a fair voice. Small well circumscribed high grade epitheliomas confined to a portion of the anterior two-thirds of a freely movable vocal cord often are curable by wide excision and electrocoagulation through thyrotomy exposure.

Thyrotomy frequently is performed for exploration of the larynx to render the neoplasm visible it often is impossible to determine preoperatively whether the growth should be removed in a conservative manner or whether laryngectomy should be done. Some well circumscribed supraglottic cancers too extensive to be extirpated through a laryngoscope, can be removed by thyrotomy although many require laryngectomy.

Briefly the technique of thyrotomy employed at the clinic is as follows. We use cervical block anesthesia. We believe that it is preferable for the patient to be conscious during the operation because general anesthesia is difficult to control when the laryngeal lumen is exposed through an external incision and because any blood that happens to trickle down the trachea is coughed up readily. After cervical block the thyroid and cricoid cartilages are exposed through a median line skin incision. With a motor-driven circular saw the thyroid cartilage then can be divided in the midline and the cut edges retracted with hooks. Incision of the underlying laryngeal mucosa exposes the interior of the larynx and the neoplasm to direct view. The lesion is excised completely with a scalpel and scissors, and the underlying bed of tissue is electrocoagulated thoroughly. The tissue which was removed is sent immediately for histologic examination by the frozen section method. If a portion of the thyroid cartilage is contiguous to the base of the electrocoagulated area it is removed with rongeurs.

This completes the removal of the growth. A tracheal cannula is inserted just below the cricoid cartilage to insure that the airway remains adequate during the postoperative heal-

ing period, a matter of 10 to 14 days. The wound is closed rather loosely with interrupted silk sutures and a split rubber tube drain is inserted subcutaneously.

LARYNGECTOMY

At the clinic, all patients who have intrinsic laryngeal carcinomas which have infiltrated deeply enough to produce fixation of one or both vocal cords but which have not metastasized to the cervical nodes undergo laryngectomy provided that their age and general condition will permit. Some low grade carcinomas which show no clinical signs of metastasis but which have perforated the thyroid cartilage or the thyrocricoid membrane or have extended into the postcricoid region can be treated by laryngectomy with a good chance of permanent cure in such cases, because the lesion is radioresistant, it would probably recur after irradiation. Furthermore we have found that the possibility of curing a patient who has a low grade malignant lesion which is undergoing metastasis to the cervical nodes is greater when block dissection of the nodes and laryngectomy are carried out than when irradiation alone is given.

As was mentioned in the discussion of thyrotomy small high grade epitheliomas on the anterior two-thirds of a vocal cord often can be removed satisfactorily by thyrotomy. However unless they are extremely small, all high grade carcinomas involving a vocal cord should be treated by laryngectomy even though there be no fixation of the vocal cord. This assertion is based on the fact that very active epitheliomas often extend far beyond the apparent limits of the growth. If a high grade malignant laryngeal lesion shows any evidence of cervical extension or metastasis, much more will be accomplished by irradiation than by surgical measures.

In performing laryngectomy we always employ local anesthesia by means of a cervical block. We do not favor use of general anesthesia for the reasons previously given in the discussion on thyrotomy. For surgical removal of the larynx, we prefer a median line skin incision to expose the thyroid and cricoid cartilages and anterior surface of the body of the hyoid bone. This incision is carried down be-

low the opening in the trachea. In order to facilitate exposure of the larynx the body of the hyoid bone is divided at the midline by means of large bone forceps and the divided ends are drawn forcibly apart by claw retractors. The attachments of the muscles at the sides of the larynx are severed and the trachea is cut across. Usually a tongue-shaped flap of laryngeal mucous membrane over the posterior part of the cricoid cartilage is elevated and left attached to the trachea; this flap ultimately aids in closure of the skin around the tracheal opening. The larynx, now detached from the trachea, is elevated and the pharyngeal mucous membrane is incised to expose the interior of the hypopharynx. By cutting across the thyrohyoid membrane, the larynx is freed completely.

On removal of the larynx a triangular shaped opening into the pharynx remains. This opening is closed by suturing its edges tightly in T shaped fashion with two rows of interrupted catgut stitches. The skin margins of the wound are sutured with silk around the trachea and the flap of laryngeal mucous membrane previously described. Mattress silk sutures are used to approximate the skin edges just above the tracheal opening. After penicillin powder has been dusted into the wound a double Penrose drain is inserted at the median line above the mattress sutures, and the wound is closed completely with interrupted silk sutures. For a few days postoperatively the patient is given intramuscular injections of penicillin.

During recent years there has been considerable controversy in the literature as to whether or not tracheotomy should be performed preliminary to laryngectomy. We believe that if the patient is young or middle aged is in good health and has a fairly adequate airway there need be no hesitation in performing laryngectomy without preliminary tracheotomy. Removal of the larynx in one stage has two advantages. First it saves the patient considerable time in hospitalization. Second it is easier in many respects to remove the larynx when the patient has not undergone preparatory tracheotomy. If the airway of a patient who has a laryngeal carcinoma is badly obstructed if his general health is poor or if

he is elderly we believe that a tracheal cannula always should be inserted in advance of laryngectomy. When a cannula is inserted removal of the larynx is postponed for 2 or 3 weeks after tracheotomy to permit all of the inflammatory reaction attending the tracheotomy to subside. It is important that there be no inflammation when laryngectomy is carried out.

SUSPENSION LARYNGOSCOPY

Destruction of certain laryngeal carcinomas with surgical diathermy under suspension laryngoscopy is advisable in selected cases. The choice of patients for this form of conservative treatment however should be made only by a laryngologist with extensive experience. Small low grade epitheliomas on vocal cords which are not fixed can be removed by surgical diathermy under suspension laryngoscopy with good results. Some laryngologists will perform thyrotomy to extirpate a very small inactive carcinoma that could have been removed by surgical diathermy under suspension laryngoscopy with much less risk and with just as good a prognosis. We wish to emphasize the fact that it is only small lesions on the vocal cords which can be treated occasionally in this conservative manner if the neoplasm cannot be brought under direct view in its entirety or if there is any question as to the extent of the growth, thyrotomy should be performed.

In cases of low grade cancer of limited extent on the anterior two-thirds of the vocal cords of elderly patients who have hypertension, diabetes or bronchiectasis or in cases in which the patient's general physical condition is so poor as to contraindicate more radical measures, treatment under suspension laryngoscopy gives the patient a greater chance of a cure than could be expected if irradiation were used.

Well circumscribed and low grade malignant tumors of the epiglottis or aryepiglottic folds or base of the tongue can be treated with gratifying results by electrocoagulation under suspension laryngoscopy. After such a neoplasm has been removed by means of surgical diathermy radon seeds often are inserted into the base of the lesion. Preliminary tracheotomy is carried out in all of these cases.

TABLE III.—CARCINOMA OF THE LARYNX 5 YEAR SURVIVAL RATES ACCORDING TO TYPE OF OPERATION

Operation	Patients*		Lived five or more years after operation	
	Total	Traced	Number	Patients traced, per cent
Laryngectomy	96.4	83	23	60
Thyrotomy with excision or diathermy	93	73	6	8.3
Suspension laryngoscopy with excision or diathermy	28	24		9.7
Total	217	180	29	72.8

*Inquiry as of January 1, 1945. Included here are only those patients operated on 5 or more years prior to the date of inquiry; that is, 1939 or earlier.

Highly malignant neoplasms of limited extent involving the epiglottis, base of tongue and occasionally the postcricoid region often can be treated under suspension laryngoscopy by implantation of radon seeds and supplementary external roentgen therapy is given. It is surprising how frequently satisfactory results are obtained in such cases with this combined form of therapy.

In treatment of laryngeal carcinoma under suspension laryngoscopy the pharynx and larynx first are cocaineized thoroughly. Then pentothal sodium is given intravenously and oxygen is administered through an intranasal tube that extends into the pharynx. Adjustment of the suspension apparatus offers an excellent direct view of the interior of the larynx. The surgeon has both hands free to insert and manipulate those instruments which are necessary to obtain a specimen for biopsy, to destroy a lesion by surgical diathermy or to implant radon seeds.

IRRADIATION

At the clinic irradiation of laryngeal carcinomas is a form of therapy reserved for high grade, radiosensitive lesions which are too extensive to warrant treatment by surgical measures. Administration of roentgen rays in fractional doses is extremely important in the treatment of some carcinomas of the larynx; many high grade tumors in which surgical operations would be of no value can be cured by fractional roentgen therapy. However we have found that only a small percentage of

laryngeal cancers are highly active growths and, in consequence we employ irradiation as a primary form of treatment rather infrequently.

The only low grade neoplasms which we treat by irradiation are those which are too extensive to be removed surgically and those which occur when the patient's age or general physical condition will not permit of surgical therapy.

In the majority of cases of carcinoma of the larynx in which intensive roentgen therapy is to be used, preliminary tracheotomy is to be recommended whether or not the patient's airway is badly obstructed by the growth. If tracheotomy is performed, there need be no concern in regard to the patient's airway should this become obstructed by postirradiation edema.

END-RESULTS OF TREATMENT

As previously stated, 568 patients were treated for carcinoma of the larynx at the Mayo Clinic from 1934 to 1943 inclusive. Of these, 446 or 78.5 per cent were treated by surgical measures—that is, by laryngectomy, thyrotomy or under suspension laryngoscopy; 122 or 21.5 per cent were treated by irradiation (Fig. 1).

Of the 446 patients who underwent operation, 213 or 47.8 per cent were treated by laryngectomy; 184 or 41.2 per cent by thyrotomy and 49 or 11.0 per cent by suspension laryngoscopy in which surgical diathermy was employed to destroy the growth or in which radon seeds were inserted into the growth. Of the 446 patients who underwent operation, 90.4 per cent were males and 9.6 per cent females. 80.9 per cent were between the ages of 45 and 69 years, 12.6 per cent were less than 45 years of age, and 6.5 per cent were more than 69 years of age.

Of all patients who underwent operation and who could be traced, 73.5 per cent survived 5 years or more without recurrence of the growth (Table III).

Of the traced patients who were treated by laryngectomy 60.2 per cent lived 5 or more years after operation; 46 per cent of the lesions were graded 1 or 2 and 54 per cent were graded 3 or 4.

Of the traced patients who underwent thyrotomy 83.6 per cent lived 5 or more years after operation. 61 per cent of these neoplasms were graded 1 or 2 and 39 per cent were graded 3 or 4.

Of the traced patients treated by surgical diathermy or insertion of radon seeds under suspension laryngoscopy 91.7 per cent lived 5 or more years after operation of the lesions in these cases, 82 per cent were graded 1 or 2 and 18 per cent were graded 3.

Of the traced patients who were treated by irradiation 6.9 per cent lived 5 or more years after operation (Table IV) of these patients 46 per cent underwent preliminary tracheotomy.

The lower survival rate associated with laryngectomy is to be expected because all malignant lesions treated by this method were large, some had extralaryngeal extensions at the time of operation and some eventually gave rise to metastasis. The high survival rate of patients treated under suspension laryngoscopy can be attributed to the fact that these patients were selected carefully and the lesions were of low grade. The low survival rate of patients treated by irradiation is to be expected since practically all of the patients had inoperable lesions, the majority of which were considered completely hopeless when first examined at the clinic. This low survival rate should not be considered as an indication of the therapeutic value of irradiation in the treatment of carcinoma of the larynx; physicians who elect the use of irradiation in cases which we would consider surgical doubtless can produce statistics which

TABLE IV—CARCINOMA OF THE LARYNX 5 YEAR SURVIVAL RATE OF PATIENTS TREATED BY IRRADIATION

Treatment	Patients*		Lived 5 or more years after treatment	
	Total	Traced	Number	Patients traced, per cent
Tracheotomy and irradiation	35	3	3	9.4
Irradiation	4	4	—	5
Total	75	7	5	6.0

*Inquiry as of January 1, 1915. Included here are only those patients treated 5 or more years prior to the date of inquiry; that is, 1910 or earlier.

show a much higher survival rate than Table IV reveals.

COMMENT

We would like to express our conviction that carcinoma of the larynx is a curable disease particularly when diagnosed accurately and early. However we believe that no one form of therapy is superior to all others in the treatment of this disease. On the contrary the type of growth in question its activity extent, and location and the age and general physical condition of the patient should be the factors which determine what type of treatment should be instituted in each individual case. In general, low grade laryngeal carcinomas should be treated by surgical measures while extensive high grade, radiosensitive tumors require irradiation. Successful surgical therapy for carcinoma of the larynx is not a question of operative technique alone but of the co-ordinated and collective efforts of the surgeon pathologist anesthetist assistants and nurses.

MONTEGGIA FRACTURES

An Analysis of Twenty-five Consecutive Fresh Injuries

FREDERICK M. SMITH M.D. F.A.C.S. New York, New York

IN 1814 Monteggia was the first surgeon to describe 2 cases of fracture of the shaft of the ulna associated with which there was an anterior dislocation of the head of the radius. This combination of injuries has since been commonly called a Monteggia fracture.

The purpose of this paper is to discuss the injury, its complications, treatment, and to give the findings and results obtained from a series of 25 fresh Monteggia fractures treated on the Fracture Service of the Presbyterian Hospital, New York, from 1929 through 1944. The discussion will be limited to fresh cases, since space will not permit of a detailed discussion of old malunited ulnar fractures with long standing radial head dislocations except to cite the inevitable result if cases are improperly diagnosed and inadequately treated.

Though not a common one the injury is also not a rarity yet it might seem so if one were to count only the fresh cases that come to the clinic for treatment. It is an extremely important type of injury because of the fact that the true diagnosis is often completely missed on clinical and even on roentgen examinations. To overlook or fail to recognize the associated radial head dislocation results in inadequate treatment, continued dislocation, possible ugly and permanent deformity, loss of lateral stability at the elbow, restriction of function and oftentimes pain.

ANATOMY

The radius and ulna are held in contact with each other at their upper and lower extremities by strong ligaments that allow the radius to rotate upon the ulna. The orbicular (annular) ligament (Fig. 3 a) surrounding the head of the radius is represented by a thickening in the elbow joint capsule and holds the radius like-

wise in contact for its articulation with the capitellum of the humerus. This ligament, however, is not so strong as the interosseus membrane that joins the radius and ulna throughout almost the entire extent of their shafts. The mechanism of injury in these cases is almost always due to the application of direct force, as for instance a fall upon the posterior aspect of the forearm. The ulnar shaft becomes fractured and its fragments are angulated or displaced forward by the force thus applied. If the radius is not fractured at the same time, the force which thus tends to shorten the ulna, must disrupt one bone from the other. The interosseus membrane being stronger than the orbicular ligament and at greater advantage owing to its longer attachment helps to lever the head of the radius away from the upper ulna and capitellum.

The mere fact that only one bone is fractured and angulated should make the physician or surgeon first examining the patient wonder what has happened to the other bone. The dislocation of the radial head is most commonly missed because of the very obvious fracture of the ulna and lack of awareness that with such a fracture one can never rule out radial head dislocation without good lateral roentgenographic views of the elbow joint. It should be *axiomatic* for the surgeon to assume that the radial head must be dislocated with this fracture unless it can be proved otherwise by adequate roentgen examination of the elbow. It may even be advisable in children to make comparative roentgenograms of the normal elbow. There should be no difficulty in determining whether or not the radial head is dislocated because on studying a lateral roentgenogram a line drawn through the long axis of the radius should pass *directly* through the center of the capitellum or its epiphysis if projected upward regardless of the amount of flexion or extension present in the elbow joint (Fig. 1).

From the Fracture Service of the Presbyterian Hospital, and the Department of Orthopedic Surgery, College of Physicians and Surgeons, Columbia University, New York.

may not include smaller peptides and are made by the digestion or hydrolysis of appropriate proteins which are then purified so as to make them safe for parenteral use. They go by various trade names, but are really solutions of hydrolyzed or digested protein. It must be emphasized that such solutions contain small molecules which possess none of the physiological properties of the large protein molecules mentioned above. They can serve only as a source for the manufacture of protein or for the nutrition of tissues requiring them. Amino acid mixtures or solutions of hydrolyzed protein cannot, therefore, be classed as blood substitutes, but merely as substitutes for the building stones of protein which normally originate in the gastrointestinal tract. However solutions of hydrolyzed protein may be made in which the process of hydrolysis is much less complete so that much larger amino acid residues are present, including particles which may even be large enough to act as colloids. Such preparations represent a meeting ground between amino acids and proteins. Some attempts have been made (Brinkman¹) to provide a protein hydrolysate which not only contains the building stones of protein which will act as a source of parenteral protein nutrition, but which also contains sufficiently large particles to act as a substitute for the albumin in the circulating plasma.

To be effective nutritionally such solutions must contain all of the essential amino acids required for normal physiological function. Whether small peptides are an advantage or not has aroused considerable interest, but can not be answered finally. At least one peptide the so-called streptogenin described by Woolley² seems to be essential for growth and cannot be synthesized by the body from amino

acids. How important it is in the maintenance of normal protein nutrition awaits further study.

Harmful reactions following the injection of hydrolyzed protein have been observed just as they have following plasma and whole blood transfusions. Any complex mixture introduced into the circulation must be prepared and given with great care and only when indicated in order to minimize such reactions. At the present time adequate preparations of hydrolyzed proteins have been extensively employed and careful study has shown that they are probably as safe or safer than plasma or whole blood transfusions. They have proved their value as a source of protein nutrition in patients who are unable temporarily to take any protein or an insufficient amount of protein by mouth. As long as surgeons are confronted with the patient who cannot take and assimilate adequate protein nourishment through the gastrointestinal tract, the parenteral injection of appropriate amino acid mixtures is the only physiological method of preventing or correcting protein starvation during such periods.

ROBERT ELMAN

GELATIN AS A PLASMA SUBSTITUTE

THE search for an effective plasma substitute during the last war led to a reinvestigation of the possible usefulness of gelatin solutions. Several groups of investigators studied different gelatins including those derived from fish, iunglass, animal hides, and beef bone. Although favorable reports appeared concerning each of these preparations, the one which was assigned optimal rating by the National Research Council, after a physicochemical and biological survey of the field was bone (ossein) gelatin of the Knox P 20 type. This preparation

INCIDENCE

Monteggia fractures are far more common in children than in adults. The ages of the 3 adults in this series was 27, 35 and 63 years respectively. The ages of the 22 children ranged as follows: 3 years (1 case), 5 years (4 cases), 6 years (2 cases), 7 years (2 cases), 8 years (4 cases), 9 years (7 cases), 12 and 15 years (1 case each). There were 12 cases with this fracture in the right arm and 13 in the left arm. Three cases of the 25 did not come under our care until 5 days after injury; a fourth case sought treatment after 2 days. All of the other 21 cases came to the Emergency Ward within a few minutes to 3 hours after their injuries. The injury is usually caused by direct force such as a fall upon the posterior aspect of the ulna or by being hit here, not infrequently by an automobile. The direct force thus accounts for the frequency of compound fractures of this type reported in the literature.

PHYSICAL EXAMINATION

The patient with a fresh injury usually holds his elbow partially flexed and in approximately mid rotation. There is a depression or concavity over the posterior aspect of the ulna at the site of the fracture. The radial head can be felt displaced toward the anterior or anterolateral aspect of the elbow. Swelling, tenderness, and ecchymosis will be present or absent as in any other acute fracture depending upon the duration of the injury, displacement of the bones, and the degree of soft part damage.

TYPES OF FRACTURE AND DISPLACEMENT

There are in general two types of deformity in fresh injuries: (1) anterior angulation of the ulnar fragments associated with anterior dislocation of the radial head (Figs. 2 a, b, c); (2) lateral angulation of the ulnar fragments associated with lateral dislocation of the radial head (Fig. 2 d). An additional possibility—(3) posterior angulation of the ulnar fragments associated with posterior dislocation of the radial head (Fig. 2 c). Watson Jones describes this third type but shows no roentgenograms. Naylor also describes it but his roentgenogram shows a fracture of the radial head in addition to its dislocation. In none of the 25 cases of fresh Monteggia fracture dis-

Fig. 1. Sketches of lateral views of bones at elbow in full flexion, midposition, and in full extension to demonstrate that longitudinal axis of radius normally passes through the center of the capitellar process or its epiphysis.

cussed in this paper has a single incidence been found of this posterior dislocation without fracture of the radial head. It is felt that posterior angulation of the ulna almost always results in fracture of the radial head or its epiphysis and that this particular type of injury is an entirely separate entity from a Monteggia fracture.

The fracture in the ulna is usually located in the upper third of the shaft but it may occur as far distal as the junction of the middle and distal thirds. It may also occur just below the olecranon process. The type of fracture may be of the greenstick variety or transverse. It may be oblique or comminuted.

The common dislocation of the head of the radius with this type of fracture is in an anterior direction. Less commonly it is seen to have been dislocated in a purely lateral direction. In such a displacement of the radial head the angulation of the ulna is always with its apex pointing laterally. Not uncommonly the radius is found to be dislocated in an anterolateral direction.

COMPLICATIONS

Compounding of the ulnar fracture is not too uncommon. Paralysis of the posterior interosseous nerve is of rather frequent occurrence of which more will be said further on. Nonunion may occur in adults at the site of the fracture, requiring later operative procedures for correction.

The greatest complicating factor in the opinion of the author is the possible and not

Fig. 2. a, b, c, Lateral sketches showing levels at which ulnar shaft may be fractured, angulated anteriorly and accompanied by anterior dislocation of the head of the radius. d, Anteroposterior sketch showing angulation of ulnar fragments in lateral direction accompanied by lateral dislocation of the head of the radius. e, Lateral sketch showing angulation of ulnar fragments in posterior direction with posterior dislocation of the head of the radius. (This particular type has not occurred in the series herein presented. With this particular angulation of the ulna, the head, neck, or epiphysis of the upper radius is much more likely to be fractured rather than simply dislocated.)

Infrequent interposition of a part or the whole of the orbicular ligament between the dislocated radial head and the capitellum which prevents its reduction by any closed manipulation

PATHOLOGY OF ORBICULAR LIGAMENT

When the radial head becomes dislocated in this type of injury the orbicular ligament may show one of three types of pathology all of which have been observed at open operation (Figs. 3, 4, 5 and 6). The ligament may become torn across and remain open. It may become torn across and fold in behind the radial head, thus preventing complete reduction of its dislocation and permitting subsequent loss of reduction. Third, instead of the radial head tearing through the orbicular ligament, it may be pulled out from beneath it and come to lie anterior to an intact ligament. In such case no reduction of the dislocated radial head is possible by closed or open methods until the ligament is incised vertically or is pried

back over the radial head by an elevator after the fashion of using a shoe horn. Roentgenograms are of little or no assistance in helping to determine the nature of the pathology of the orbicular ligament.

The following quotations from the operative reports of 2 cases will serve for illustration by describing the pathology and method of reduction of the radial head.

"The radial head lay in contact with the capitellum and the anterior portion of the capsule and the orbicular ligament was intact except for the lower margin of the latter which presented a sharp free edge. The radial head evidently had pulled down and out of the orbicular ligament. Reduction was performed by strong traction increasing the anterior angulation and firm pressure made over the radial head while the capsule was lifted over it with an elevator. (Case 6.)

"The radial head had torn through the capsule distal to the orbicular ligament and had poiled out from beneath it. It was impossible to reduce the radial head without first dividing the orbicular ligament. The posterior interosseous nerve was displaced anteriorly by the dislocated radial head which caused pressure upon it.

Fig. 4, Sketch of anteroposterior aspect of elbow joint showing possible sites of tear in capsule which allows dislocation of radial head a, through main capsule b, below orbicular ligament.

Fig. 5 Sketch of anteroposterior aspect of elbow joint showing how radial head may become dislocated anteriorly by tearing capsule distal to orbicular ligament and pulling out from beneath it. The radial head then lies upon the intact main portion of the ligament and the latter must be incised in order to bring about reduction of the radial head.

Fig. 6 Sketch of lateral aspect of elbow joint showing an anteriorly dislocated radial head (with Monteggia fracture). The radial head may lie anterior to an intact or partially intact orbicular ligament. The posterior interosseous nerve may be subjected to pressure or stretching by the displaced radial head before it enters the interval between the superficial and deep layers of the supinator brevis muscle to pass into the posterior compartment of the forearm. This was noted in Case 14 of this series, on admission patient showed no paralysis of this nerve, but 3 hours later did show paralysis. No attempt had been made to manipulate and reduce the fracture and dislocation.

This patient had no evidence of nerve palsy on admission but developed it after 3 hours and was operated upon 18 hours after admission (Case 14)

TREATMENT

It has been stated by Boehler that all of these radial head dislocations can be reduced

and held reduced by closed manipulation and immobilization in plaster. This would seem very doubtful in view of the above described pathology and one might doubt very much if the cases analyzed in this article had a monopoly on such pathology whether the patient is treated by open or closed methods.

There is no single method of treatment applicable to all cases. Many undoubtedly can be reduced by closed methods, remain reduced and achieve excellent results. These are the cases in which the ulnar fragments can be reduced and locked and in which the orbicular ligament is open and not folded in behind the radial head. Reduction should be tried by traction with the forearm extended. Firm pressure should be applied over the anterior aspect of the angulated ulnar fragments and as well over the radial head. When the latter slips back into place, the elbow should be flexed and then extended again. If the orbicular ligament is not interposed the radial head should stay in place provided the ulna is adequately reduced (Fig 7 a b c). If it remains in position the forearm should then be flexed to 90 degrees and immobilized in an anterior and posterior molded plaster splints extending from the axilla to the metacarpophalangeal joints. The position of the radial head and of the ulnar fragments should receive weekly or biweekly roentgenographic check ups, and if either one becomes displaced open operation should be performed and internal fixation used. If the original reduction has not been completely successful from the standpoint of either perfect reduction of the radial head or of the ulna, we believe that open reduction should be performed.

Not infrequently even with successful closed reduction of both lesions, a loss of position of one bone occurs with resultant loss of position of the other. The ulnar fragments tend to bow anteriorly and toward the radius and in an adult if not corrected, show a strong tendency to develop nonunion or malunion. We believe that all adults with this injury should be operated upon have the ulna plated rigidly where possible and the radial head reduced and the orbicular ligament repaired (Fig 8 a, b c Fig 9 a, b). If the ulnar shaft is so comminuted as to make rigid fixation by a plate and screws an impossibility it may be advisable to resort to intramedullary fixation by means of a Steinmann pin Kirschner wire or a small caliber Kuntschner nail inserted downward through the olecranon process. If this form of fixation is to be employed, it is advisable to expose the fracture site rather than take

a chance of guiding the pin "blindly" into the medullary canal of the main lower fragment.

It is justifiable to attempt closed reduction in young children but if this is not completely perfect or does not remain so with frequent check ups, they should not be allowed to go more than 10 days or 2 weeks without operative correction. Small narrow stainless steel forearm plates are the best form of internal fixation for the ulna. It is just as important to prevent subsequent bowing of the ulna in a child as in an adult if subsequent subluxation of the radial head is to be avoided (Fig. 10, a b c).

Compounding of the ulnar fracture should call for immediate and thorough operative débridement and lavage with normal physiological saline solution. The fracture should be anatomically reduced and rigidly immobilized. There is no contraindication to the use of internal fixation provided the surgeon is properly equipped and trained to use it and provided that the wound is of less than 12 hours' duration and not infected. The wound should be very loosely packed open with fine mesh, plain gauze rather than taking a chance on primary closure. After 5 or 6 days the patient should again be taken to the operating room, the wound inspected and if clinically clean, a secondary closure should be done after mobilizing the skin flaps in order to prevent the creation of any tension in the wound. Penicillin may be given *only* as an adjunct to thorough surgery but *never* as a substitute. Compound fractures in the upper extremity are entirely different problems from those in the lower extremity and very rarely become infected if proper surgical principles and thorough and adequate débridement are carried out.

OPERATIVE INCISION

The choices of incision for the operative approach are several in number. The ulnar fracture site may be approached through an incision directly along the posterior subcutaneous crest of this bone and the radial head dislocation may be approached through a separate anterior incision of the Z-type, care being taken to avoid cutting directly across the flexion crease of the elbow in order to avoid development of a keloidal contracted skin

Fig. 7

Fig. 8.

Fig. 8. Case 16. a, Original lateral view of forearm and elbow. b, Lateral view after closed reduction. Ulnar fragments are improved, but not perfectly reduced. Radial head appears still dislocated. The diagnosis was initially missed. The elbow was operated upon 4 days later and a portion of the anterior capsule was found interposed between the radial head and capitulum. c, Lateral view 2

Fig. 9.

years after open reduction and fixation of ulna with three screws. (This form of internal fixation is not the most ideal. A narrow plate and screws would have been more satisfactory.) Radial head remains reduced.

Fig. 9. Case 24. a, Lateral view showing ulnar fracture at level of midshaft with anterior angulation. Radial head is dislocated anteriorly. Note how latter could easily have been overlooked had the elbow joint not been included on the film. b, Lateral and anteroposterior views 3 years and 4 months after open reduction and internal fixation of ulna with plate and screws. Radial head remains in normal position.

Fig. 10. Case 14. a, Original lateral view showing greenstick fracture high up in upper third of ulna with forward angulation and with anterior dislocation of radial head. (The radial head, as found at operation, to have pulled out from beneath the orbicular ligament.) b, Original anteroposterior view of same case showing ulnar fragments angulated laterally as well as forward and with lateral as well as forward dislocation of the head of the radius. c, Lateral view—five years and 5 months after operation. An internal fixation was used to maintain position of the ulna after reduction. It was necessary to divide the orbicular ligament to permit reduction of the radial head and this was then sutured. Position of the ulnar fragments reangulated slightly and partial subluxation of the radial head recurred.

scar. The deep fascia is incised longitudinally in the interval between the brachioradialis laterally and the biceps and brachialis anticus muscles medially. As this interval is deepened the superficial radial and posterior interosseous nerves are seen branching from the main radial (musculospiral) nerve. Since all muscular branches from the nerve pass in a lateral direction, the whole nerve should be retracted laterally in order not to harm any of these. The dislocated radial head and anterior capsule of the elbow joint are then readily seen and reduction and operative repair can be easily carried out as is necessary.

A single incision as described by Speed and Boyd, may be used and is an excellent one for taking care of the ulnar fracture and radial head dislocation at the same time. This incision begins about 1 inch above and lateral to the tip of the olecranon and then passes distally along the posterior aspect of the ulna as far as necessary. The muscles attached to the lateral side of the ulna, including the supinator muscle, are elevated subperiosteally thus exposing the radiohumeral joint. If care is taken to hug the ulna with the periosteal elevator there is no risk of injuring the posterior interosseous nerve which lies between the

superficial and deep layers of the supinator muscle. Through this incision it is thus possible to plate the ulna and to repair the orbicular ligament after reducing the dislocated radial head.

ANALYSIS OF CASES

There were 25 fresh Monteggia fractures in this series. Three were in adults, in one of which the fracture was compounded, the victim having been struck by a car. The majority of the children were injured at some form of recreation roller skating being the single greatest factor. Posterior interosseous nerve palsy was noted in 6 cases on admission. Five others developed palsy following operation. All of these patients with nerve complications recovered. The original diagnosis was correct in 21 cases and missed in 4. Two of these were in the first 2 cases of the series. One was picked up after a week but refused operation (Fig. 11) and did not return after 1 month of treatment. The second was not picked up until he returned to the follow up clinic 4 months after injury (Fig. 12). This case has been subsequently followed for almost 13 years. The radial head is still dislocated and prominent. He works as a clerk without handicap but

Fig. 13.

Fig. 11. Case 1. Anteroposterior and lateral views 2½ weeks after injury showing transverse type of fracture in ulna with angulation in anterior direction and with complete dislocation of head of radius. Early callus is seen at ulnar fracture site. This patient refused operation.

Fig. 12. Case 2. Lateral view 7 years and 9 months after injury showing late deformity of ulna, which has healed with persistent anterior dislocation of the head of radius. This latter dislocation was originally overlooked

and not discovered until it was too late to correct. (Late unreduced radial head dislocations if causing pain or disability may be benefited by resection of the radial head.)

Fig. 13. Case 13. Original lateral view showing simple greenstick fracture of ulna with anterior angulation and anterior dislocation of head of radius. At operation the anterior joint capsule was found interposed between the dislocated radial head and the capitellum. The ulnar fragments were fixed with a plate and four screws.

Fig. 14, left. Case 7. Original lateral view showing oblique type of fracture unusually high up in ulna and with anterior dislocation of head of radius. This patient was operated upon and the orbicular ligament was found open. The ulnar fracture was fixed internally with an aluminum plate and four screws.

Fig. 15. Case 22. Original lateral view showing fracture of upper third of shaft of ulna with slight comminution and with complete antero-dislocation of head of radius. Note also partial separation (fracture) of the distal radial epiphysis.

was unable to pass the physical examination for the sanitation department of the city of New York due to weakness and pain on heavy lifting. The 2 remaining patients who failed to have made on admission a diagnosis of ra-

dial head dislocation were picked up the following day and operated upon at 4 days (Fig. 8 a, b c) and 1 day respectively both with excellent results after 7 and 5 year follow ups respectively (Figs. 13, 14 and 15).

TABLE L.—SUMMARY OF CASES—Continued

Case No. Age in years	Duration of injury	Associated conditions or injuries	Original diagnosis		Primary treatment		Secondary treatment	Internal fixation of ulna	Orbicular ligament untears or folded; if behind dislocated radial head	Radial nerve palsy		Follow-up and result	Remarks
			Correct	Incorrect	Closed	Operative				Before operation	After operation		
80	hr	—	+			+	Operation stat for radial head. Ulna reduced closed. Operation at d. for ulna.	Plate and 4 screws	+	+		3 yrs. 7 mos. Good	Radial nerve recovered 1 1/2 weeks. Slight dorsal bowing of ulna. Extension 6 Row limited 5°
98	hr	—		+	+		Operation at day	Plate and 6 screws				4 yrs. 10 mos. Excellent	
105	1 1/2 hr	—	+			+	Operation stat.	Plate and 6 screws	+			4 yrs. 9 mos. Excellent	Refraction of ulna through screw hole at 3 mos. Radius not rediolated. Operation, ulna replated. Plate removed 3 mos. later
9	hr	Compound wrist and fracture of lower radial epiphysis	+				Operation stat. for wrist and ulnar shaft. Radius reduced closed	Plate and 4 screws				4 yrs. Excellent	Elbow perfect. Has growth disturbance at wrist
8	1 1/2 hr	Separation of lower radial epiphysis	+			+	Operation stat.	Plate and 6 screws				None	Died after operation of aspirated vocalium
37	days	—	+		+							1 yr. 10 mos. Excellent	
49	1 1/2 hr	—	+			+	Operation stat.	Plate and 6 screws	+			1 yr. 4 mos. Excellent	
503	1 1/2 hr	Compound tibia. Head and subcondylar injuries	+		+							None	Good reduction of ulna and radial head, but subsequently lost position of ulnar fragments in plaster at 3 wks. Transferred to Mental Hospital 1 1/2 wks.

In 16 of the 25 cases closed reductions were attempted as the primary treatment and 7 of these patients subsequently were operated upon either for loss of position of the ulna or radius. In 9 cases, including 2 compound fracture cases open reduction was the primary treatment. One compound fracture had only the ulna treated originally by operation and 14 days later open reduction was done on the radial head. One other patient had an open reduction performed on the radial head the same day of injury but a closed reduction only was done on the ulnar shaft. The ulna subse-

quently became angulated and at 10 days open reduction with plating was performed on it. This patient after 7 1/2 years still has a slight prominence over the ulnar fracture site and a loss of 5 degrees of full elbow extension. The total number of operative cases was 16 and internal fixation of the ulnar fragments was performed in 12.

As for the orbicular ligament pathology noted at operation in 10 cases there was found either an untorn ligament with the radial head pulled out from beneath it or a torn ligament or capsule interposed between the radial head

and capitellum or lesser sigmoid notch of the ulna.

The average duration of treatment for all cases was 8 weeks.

All but 4 of the 25 cases have been followed for periods of years, the average being $5\frac{1}{2}$ years. The more recent cases were for a shorter period of course. The results in the 21 followed cases have been completely perfect from the standpoints of anatomy function and economic status in 13 cases and good to excellent in all the others except in Case 2. None of the cases resulted in nonunion. All of the cases with nerve injury recovered full function. One case had a possible osteochondritis in the elbow after 6 years and 9 months as noted by a clicking noise on pronation and supination.

Two (Cases 16 and 20) subsequently re-fractured the ulna through the site of one of the screws used for internal fixation. In Case 16 patient did this 4 years after the original trauma and he was treated for this second injury conservatively with plaster splints. There was no redislocation of the head of the radius. In Case 20 the ulna was re-fractured 13 months after the original injury but the radial head was not redislocated. Owing to the fact that the plate used for internal fixation originally also became broken he was re-operated upon the broken plate and screws removed and the ulna was plated again. Solid bony union occurred and this second plate was removed 3 months later. (See Table I.)

SUMMARY

1. Early recognition of the radial head dislocation is the most important part of the diagnosis in Monteggia fractures

2. Early treatment with completely perfect reduction of the fracture as well as the dislocation is necessary and this must be checked frequently by roentgenograms to rule out secondary loss of position of either bone.

3. Open reduction is frequently necessary if the ulnar fragments cannot be held in anatomical position.

4. Open reduction is often absolutely necessary to make possible reduction of the radial head and for removal of interposed ligament or capsule.

5. If open reduction is to be performed, it should be done early and preferably with rigid internal fixation applied to the ulna.

comes from the manufacturer in a pyrogen free physiological saline solution in a sealed container ready for use. It has been administered to many hundreds of patients, as well as to large numbers of animals, and gives promise of being a valuable plasma substitute as far as its use in restoration and maintenance of plasma volume is concerned.

In physicochemical properties gelatin differs in several respects from natural plasma protein. Whereas the plasma proteins may be grouped into a few classes of molecules each of uniform size and shape gelatin comprises a broad spectrum of molecular sizes each having a diameter of about one half that of the plasma proteins but varying greatly in length. The shorter molecules readily permeate biological membranes but the longer ones are retained. Solutions of gelatin which have been least degraded through cooking or autoclaving will contain larger proportions of very long molecules; these preparations tend also to have a higher viscosity and will gel at room temperature. However they enjoy a considerable physiological advantage in shock therapy over the more degraded less viscous preparations, because the long asymmetrical molecules tend to be retained longer within the circulation maintain plasma volume longer and are more efficiently metabolized.

A 6 per cent solution of Knox P 20 gelatin possesses a colloid osmotic pressure approximately 50 per cent greater than that of plasma. Therefore when administered to normal subjects it tends to cause a transient hemodilution by pulling in water from the tissues. Its hemodiluting effect is approximately equivalent, gram for gram with human serum albumin. However unlike albumin the smaller and more oncologically active molecules of gelatin are rapidly excreted through the kidney so that the hemodiluting effect may not be as long maintained as with albumin. This differ-

ence does not appear to be of great practical importance in therapy of hemorrhagic shock because an animal or patient who although in shock is not suffering from prolonged depletion of protein stores appears to mobilize new plasma protein with sufficient rapidity to compensate for the gelatin excreted. Comparative studies have shown gelatin to be at least as effective as plasma in restoring circulation after severe hemorrhage with or without prolonged hypotensive periods and it has been employed in the shock phase of severe burns with excellent results. However it must be emphasized that *neither plasma nor gelatin is more than a temporary and partial substitute for whole-blood replacement in shock due to blood loss*.

Gelatin which has been properly prepared is nonpyrogenic and nonantigenic—the incidence of reactions following its administration to patients has appeared to be substantially lower in practice than with other colloids. Unlike acacia, pectin and other large molecular carbohydrates which have been employed as infusion colloids gelatin does not accumulate in the liver and other organs and no histopathological changes appear following the administration of large amounts over prolonged periods. Furthermore gelatin may be given without fear of transmitting the virus of homologous serum jaundice which may be present in blood and plasma. It may be kept for long periods of time without refrigeration and can therefore be readily available for emergency use in accident wards, physician kits and catastrophe depots. It also has the great advantage of low cost, the cost being less than 10 per cent of that of commercial human plasma.

However, there are some disadvantages of gelatin which should be pointed out. In the first place the most suitable preparations are those which will gel after standing at room

NEURILEMMOMA OF THE PHARYNX

C EVERETT KOOP M.D., H ERNEST JORDAN M.D. and
ROBERT C HORN M.D. Philadelphia, Pennsylvania

WHEN Stout proposed the name neurilemmoma¹ in 1935 for the specific tumor of peripheral nerve sheaths described by Verocay in 1910 (6-7) there had been 194 cases reported in the medical literature in the previous 100 years designated as neurinoma, perineural fibroblastoma, Schwannoma, peripheral glioma and by other less common descriptive terms. To these Stout added 52 tumors from his own experience indicating that the tumor was not as rare as might be supposed from the small number of previously reported cases. Since that time, the numerous reports of the occurrence of neurilemmoma have confirmed his impression.

Although a neurilemmoma theoretically can arise in any portion of the body where a nerve sheath exists, the great majority of reported tumors have been described in specific anatomical regions where one is apt to find them with relative frequency. One of the more rare sites for the discovery of a neurilemmoma has been the pharynx. The number of reported cases is now 6 (1-2-5) including 3 which are more specifically retrolaryngeal (2-3-4).

From the Surgical Service, the Otolaryngological Service, the Laboratory of Surgical Pathology and the Tumor Clinic of the Hospital of the University of Pennsylvania.

Fig. 1. Gross appearance of the tumor in Case 1. The tumor has been bisected and the photograph shows the cut surface.

During the past 9 years we have removed 5 neurilemmomas (3 in the past 3 years) which presented in the oropharynx or nasopharynx. Because of the comparative rarity of the neurilemmoma in the pharynx and the fact that several of these tumors, although too large to be removed endorally, were successfully removed through the neck, it seems worthwhile to record these cases.

Tumors in the nasopharynx are more often malignant than benign and of the benign tumors, neurilemmoma is certainly one of the less common. Inasmuch as the neurilemmomas are encapsulated by an expanded perineurium unless the tumor is also traversed by bundles of fibers of the peripheral nerve itself, the surgeon may overlook the presence of the nerve from which the tumor arose. For this reason it is often difficult to know the actual site of parentage of a neurilemmoma even after extirpation.

The precise point of origin of the tumors reported here is not known in each instance. However, all of the patients had initial symptoms referable to the pharynx, all had visible tumor presenting in the pharynx, and all came to operation either by the endoral or external approach after seeking otolaryngological consultation. It is quite possible, nevertheless,

Fig. 2. Photomicrograph of the tumor in Case 1. Antoni types I and II tissue are both seen. Hematoxylin and eosin $\times 70$. The inset shows nuclear palisading $\times 140$.

Fig. 3. Gross appearance of the tumor in Case 2. The photograph on the right shows the external aspect before sectioning, that on the left the cut surface.

that several of these tumors may have had their origins in the deep nerves of the neck, and with growth expanded under the pharyngeal mucosa. Neurilemmomas have been reported to have definite beginnings in the cervical sympathetic, in the roots of the spinal nerves and trunks of the cervical plexus and in the spinal accessory and vagus nerves. Neurilemmomas arising from any of these sites finally could present themselves in the pharynx.

REPORTS OF CASES

CASE 1. N. F., a 49 year old white female, complained of a mass in the left side of the neck of 8 years duration. Recently the tumor had been associated with occasional pain in the ear and a smaller mass had appeared in the tonsillar region.

Physical examination revealed a hard nontender mass in the neck half the size of an orange which extended from the left ear to the level of the larynx. A similar mass 3 centimeters in diameter projected into the left side of the pharynx behind the posterior tonsillar pillar.

Röntgen examination of the neck showed, in addition to the soft tissue mass, questionable evidence of a destructive lesion involving the third to the sixth cervical vertebrae. A biopsy of the pharyngeal aspect of the tumor (Dr. Karl M. Hovner) led to a diagnosis of neurilemmoma.

During the succeeding month intensive roentgen therapy was administered to the tumor in divided doses without apparent benefit. At the end of the roentgen therapy the pain in the ear was almost constant and the patient complained of difficulty in swallowing.

The tumor was removed (Dr. J. E. Rhoads) under endotracheal anesthesia through a lateral cervical approach. The removal was apparently complete except for a fragment of tumor tissue in the plane near the biopsy site. Convalescence was uneventful except for temporary partial paralysis of the hypoglossal and glossopharyngeal nerves. The patient was last contacted about 2½ years after operation, at which time there were no complaints or evidences of recurrence.

Pathologic examination. The biopsy (S.P. No. 50031) showed an unusually cellular tumor which also contained abundant fibrillar material. Types A and B tissues of Antoni were both present and peculiar palisading was a conspicuous feature.

Grossly the excised specimen (S.P. No. 50655) was a kidney-shaped, encapsulated tumor which measured 7 by 5 by 2 centimeters. It was firm and the cut surface was yellow and translucent, showing a few hemorrhagic areas. White, fibrous trabeculae partially separated the tumor into several lobes (Fig. 1). Microscopic examination revealed a picture essentially similar to that of the biopsy. The cellularity was striking and many of the cells were quite large and irregular (Fig. 2). Mitotic figures were not observed.

CASE 2. F. S., a 30 year old colored female, had complained of difficult and painful swallowing for 14 months. One year previously she had been studied in the Department of Otolaryngology for this same

complaint. Biopsy of a pharyngeal mass detected at that time revealed no evidence of tumor. The Wassermann reaction was found to be positive but the pharyngeal tumor enlarged progressively despite intensive antituberculous therapy until it threatened to obstruct her airway as well as prevent swallowing.

Physical examination revealed a hard "egg-sized" mass presenting on the left side of the posterior pharyngeal wall behind the tonsillar fossa. It extended up into the nasopharynx and down to the epiglottis and was not freely movable. An indefinite prominence was noted in the left submandibular region. The pupils were irregular but reacted to light and in accommodation. Vision in the left eye was poor.

There were no other significant physical findings. At operation (C.E.R.) under endotracheal anesthesia the tumor was approached through an incision parallel to the medial border of the left sternocleidomastoid muscle. The tumor lay beneath some of the constrictor muscles of the pharynx and was shelled out by blunt dissection with the aid of a finger in the pharynx. It was encapsulated and seemed to arise from a small nerve trunk which was not definitely identified. The integrity of the procedure was maintained throughout. Three months after operation there was no evidence of recurrence and the motility of the pharynx was normal but the enophthalmos and ptosis persist.

Pathologic examination (S.P. No. 57729) Grossly the specimen was a soft encapsulated ovoid tumor measuring 4.5 by 3 by 2.5 centimeters. Section showed a peripheral rim of translucent gray tissue but most of the tumor was friable and hemorrhagic (Fig. 3). Microscopic examination revealed the typical A and B tissues of Antoni the former predominating. The tumor cells had small, dark, elongated nuclei, often arranged in palisade formation. Hyalinization and hemorrhage were prominent and many of the blood vessels were surrounded by thick collagen. An additional section prepared from what was thought to be the nerve of origin showed numerous ganglion cells in addition to nerve fibers.

CASE 3. I.T. a 50 year old colored woman complained of pain about the left thigh hip and lumbar spine, which had been present since she was injured in an automobile accident 6 months previously. Questioning elicited the fact that she had been having difficulty swallowing for the past several months. Physical examination showed in addition to her orthopedic findings, a mass about 3 1/2 centimeters in diameter in the right posterolateral wall of the oropharynx. It extended down into the upper part of the laryngopharynx. The right posterior tonsillar pillar was pressed forward and the tonsillar fossa was obliterated. The tonsil showed marked atrophy on this side. The mass was firm circumscribed and covered by normal mucosa. Roentgen studies showed lymph node enlargement. Roentgen studies showed a soft tissue mass in the region described without evi-

dence of bone destruction. Chest films revealed changes in the right lower lung field which suggested pleural thickening together with the presence of some fluid. The left lower lung field was also somewhat hazy and it was impossible to rule out the possibility of metastatic involvement.

On February 18 a biopsy of the pharyngeal mass was taken but the fragments submitted were too small for adequate examination. One area suggested the possibility of a neurilemmoma. Two subsequent biopsies were taken but none of them were satisfactory. It was the consensus that this was most likely a benign, radioresistant tumor and that the treatment of choice was surgical removal. After consultation with the surgical service it was decided to attempt removal by the oral route. A preliminary tracheotomy was done in preparation for the operation and the tumor was removed through the mouth under pentothal anesthesia. The tumor was well encapsulated and was shelled out readily by blunt dissection. Very little bleeding was encountered. The edges of the pharyngeal mucosa were approximated with catgut sutures. Penicillin had been started preoperatively and was continued through her postoperative course which was uneventful.

Pathologic examination (S.P. 54573) Grossly the specimen was an encapsulated tumor mass measuring 5.5 by 4.0 by 2.5 centimeters. Much of it was occupied by a central cystic cavity. Microscopic examination revealed that dense, relatively acellular fibrous tissue made up most of the cyst wall. Hyalinization evidenced of old hemorrhage and cystic degeneration were unusually marked and there were also foci of chronic inflammation. Despite the extent of these secondary changes, there were areas where the clear palisading and the loose myxoma like tissue characteristic of the neurilemmoma, could be seen (Fig. 4). Several clusters of foam cells were noted in the periphery. A few ganglion cells were observed in the periphery of the tumor. These were presumed to be accidental inclusions, from a sympathetic ganglion or nerve which gave rise to the tumor.

CASE 4. D.O.R. a 55 year old white male, complained of difficulty on swallowing and examination disclosed a large mass on the posterior faucial pillar just behind the size and shape of a hen's egg and it was about the size and shape of a hen's egg and was covered by normal mucosa. The diagnosis of sarcoma had been made elsewhere and x ray therapy had been instituted. This apparently had been with no beneficial effect. A biopsy was planned but at operation the mass shelled out so readily that it was decided to administer a general anesthetic and remove the entire lesion. As the operation progressed it was discovered that the mass extended to the region of the carotid sheath and dissection became more difficult. One large vessel had to be ligated. This was apparently the internal carotid although it was of unusually small caliber for that vessel. The mass was eventually removed and the patient a con-

The hospital record of this patient was not available and the clinical abstract was taken from a report by Dr. Karl M. Hoover

dition appeared to be good when he was returned to the ward. However he never regained consciousness and died 24 hours later. Permission for autopsy was not granted and the exact cause of death was not determined.

Pathologic examination (S P 33516) No gross description is available. Microscopic examination revealed an encapsulated tumor composed in part of compact fibrillar tissue and in part of loose textured areas poor in fibers. The cells had small, elongated and deeply stained nuclei, often arranged in palisades. Hyalinization and microcystic degeneration were striking features.

CASE 3. C.L. a 30 year old white male, was well until he developed an acute upper respiratory infection. He consulted his family physician who discovered a swelling in the right posterior pharyngeal region which he diagnosed as a peritonsillar abscess. The patient was kept in bed for 2 weeks and although all signs of the upper respiratory infection had subsided there was no change in the size of the pharyngeal mass. Three weeks after the onset of his illness, his tonsils were removed but there was still no change in the size of the mass, and the patient was referred to the University Hospital.

Physical examination was negative except for the mass in the right side of the pharynx. It was smooth, nontender, nonfluctuant and covered by normal mucous membrane.

X-ray examination of the chest and neck was reported to show "a large soft tissue tumor occupying the oropharynx and nasopharynx."

The tumor was removed by the oral route (Dr. Karl M. Houser). There was considerable bleeding which necessitated packing of the cavity. Following removal of the packing there was no further bleeding or respiratory difficulty and thereafter convalescence was uneventful except for a transient right Horner's syndrome.

Pathologic examination (S P No 29898) No gross description is available. Microscopic study showed the greater part of the tumor to be composed of relatively acellular collagenous tissue. Microcystic degeneration was noted. Palmsading of the nuclei was a striking feature (Fig 5).

The final diagnosis of these tumors cannot be made without histologic examination. The comparative frequency of the nasopharyngeal neurilemoma in our recent experience, however led to the correct diagnosis preoperatively in 2 cases.

If the tumor visualized and palpated in the pharynx by endoral examination is of sufficiently small size to be removed safely through the mouth preliminary biopsy in our opinion is not indicated. With the larger tumors, of diameter too great to permit removal safely through the mouth we believed, at first, that preliminary biopsy was in order. However

biopsy of large tumors through the pharyngeal wall is not always satisfactory and safe. Furthermore, the biopsy site is a potential pathway for infection in the neck at the time of biopsy or later removal of the tumor by the lateral cervical approach. Our 2 most recent patients were operated upon (one through a lateral cervical approach and one endorally) on the basis of clinical diagnoses, subsequently proved to be correct. Biopsies were attempted in both cases but were of insufficient depth to be diagnostic.

In spite of the fact that benign tumors are less common than malignant ones in the nasopharynx, the signs of benignity of the neurilemmomas here reported were definite. The round or fusiform shape of the tumors, their apparent encapsulation and the fact that they do not ulcerate the pharyngeal mucosa or fix themselves to it usually are demonstrable signs.

Ehrlich and Martin recommend aspiration biopsy of these tumors and diagnosed a retropharyngeal and a retrotonsillar neurilemoma by this method. Neither patient was operated upon however because it was considered as unjustifiably hazardous procedure for benign tumors with minimal symptomatology.

Difficulty in swallowing was the presenting symptom in 3 of our 5 patients. Four were also conscious of a mass but the presence of a mass in itself caused but one patient to seek medical care. Two of the tumors were found in patients who were under medical care for other reasons. Direct questioning disclosed that one of these patients had been aware of dysphagia but the other had no previous complaints attributable to the tumor. One patient had unequal pupils before operation. The histories presented by our patients would suggest that small, benign, asymptomatic neurilemmomas may eventually cause trouble and for that reason should probably be removed when encountered except in the face of specific contraindications. Experience with Case 1 emphasizes again the resistance to radiation of the neurilemoma, an observation which has been pointed out previously (2).

Three of the tumors in this group are characteristic examples of the neurilemoma (5). A fourth Case 1 has the usual histopathologic

features of the specific tumor of nerve sheath origin and is readily recognizable as such although it is unusually cellular and the cells are frequently large, irregular and hyperchromatic. However mitotic figures were not observed and this patient has had no further difficulty in the 2½ years since operation.

The fifth tumor Case 3 presents diagnostic difficulties. Similarities to the characteristic structure of the neurilemmoma are limited to fragmentary portions of the lesion. We believe that the degenerative changes so commonly seen in tumors of this type have in this instance, been sufficiently advanced and wide spread almost to obliterate the underlying structural features. The ganglion cells occasionally encountered in the periphery of this tumor are regarded as most likely to be inclusions from a sympathetic nerve or ganglion of origin rather than an integral part of the neoplasm.

SUMMARY

Five instances of neurilemmoma of the pharynx are reported bringing to 11 the total num-

ber recorded in the literature. Four of the tumors in this group caused dysphagia, 1 of them being associated with respiratory difficulty in addition. In the 2 cases most recently encountered the correct diagnosis was made preoperatively on the basis of clinical findings. We believe that even small asymptomatic neurilemmomas should be removed surgically since they may produce symptoms as they enlarge. Three of the tumors in this group were removed endorally, 2 through a lateral cervical approach. There was 1 postoperative death.

COMPARATIVE HEMATOLOGIC FINDINGS IN NORMAL, SPLENECTOMIZED AND SPLEEN-TRANSPLANTED DOGS

ALFRED L. COPLEY M.D., PAUL L. STEFKO, B.A., and
JANET NAYLOR, B.A. New York, New York

THE transplantation of the spleen as well as of other organs with anastomosis of blood vessels has been attempted by several investigators. Carrel (6) reported autotransplantation of the spleen of a dog and found that it remained in normal condition for more than 20 months after the operation. In another dog however the transplanted spleen had completely disappeared about 3 months following operation. On exploratory laparotomy 2 weeks after operation occlusion of the artery has been found to be probable (7). The anastomosis of the vessels was made by the suture method of Carrel, and no account was found in the literature that such anastomosis of the transplanted spleen was made by a nonsuture method. The first described nonsuture method for organ transplantation has been given by Ullmann who used the prosthesis of Payr for anastomosing the vessels of the kidney with the carotid artery and the jugular vein. The prosthesis of Payr consists of magnesium tubes. Although Carrel succeeded in transplanting spleens, he did not attempt to transplant a second spleen. We employed the nonsuture method of Blake-more Lord and Stefkó with vitallium tubes as prosthesis of the splenic artery and vein to the femoral or middle colic vein respectively.

In an attempt to learn more about the physiologic functions of the spleen we inserted this organ in other sites of the circulatory system and also attached a second spleen by homotransplantation in dogs. The displaced and sometimes increased spleens were studied by their effect on certain hematological tests. For the appraisal of the hematologic data we found it necessary to establish control values on a large number of healthy mongrel dogs. These findings were obtained in 20 compara-

tive series on 16 dogs. In addition we present hematologic data secured at various intervals of time following splenectomy of healthy dogs.

A. Operative methods Through an upper left rectus incision the great omentum is carefully displaced to the right. Exposure of the spleen is best accomplished by packing off the stomach medially. With the proper retraction the spleen presents itself in the wound and is readily delivered. The splenic artery and vein are identified isolated ligated and divided between clamps. The remainder of the pedicle is then successively clamped divided and ligated. The spleen is removed and is immediately irrigated via the splenic artery with 100 cubic centimeters of warm physiologic saline containing 10 units of sodium heparin per cubic centimeter. This step is important and may mean success or failure of the procedure to follow.

In another animal the skin of the lower abdomen and upper inner thigh is carefully prepared. The operative field is cleansed with soap and water treated with benzene, and carefully washed with alcohol and ether. It is then painted twice with iodine, and alcohol is applied to remove the latter.

A longitudinal incision, 7 centimeters in length is made high in the thigh, starting 3 centimeters above the inguinal ligament and following the course of the artery downward. If the initial incision has been correctly placed, the muscle groove between the sartorius and abductor longus muscles can readily be identified. Access to the great vessels can easily be gained. The artery and vein are freed for a distance of 6 to 8 centimeters. They are individually clamped with rubber shoe clamps at the proximal end and doubly ligated with medium silk at the distal end and then divided. The vessels are thoroughly irrigated with physiologic saline and then affixed with vitallium tubes (4). The spleen is now brought into

From the Laboratory of Cellular Physiology Department of Biology, New York University, New York, and the Department of Surgery and Gynecology, School of Medicine, University of Virginia, Charlottesville, Va.

the field. The splenic artery and vein are anastomosed to the femoral artery and vein respectively. It is important at this point not to damage the intima of either the splenic vessels or the femoral vessels for such trauma may lead to thrombosis.

A small incision is made in the lower abdomen just above the inguinal ligament. This incision should be long enough to facilitate the entrance of the spleen into the abdominal cavity. Care must be taken not to cause any angulation or tension on the splenic and femoral vessels for this may lead to occlusion of the anastomoses. Such partial or complete occlusion may initiate thrombosis as we observed in a number of operations previously. The vessels are swung over the inguinal ligament. In this manner the palpatory method is employed to test the patency of the vessel daily.

The wound is closed by first closing the peritoneum with a continuous suture of fine silk and then approximating the fascia, subcutaneous tissue, and skin by means of interrupted sutures of fine silk. A collodion dressing is applied to the wound.

B Hematological methods. The red and white blood counts and differential smears were made according to standard procedures. The sedimentation rate was done according to Westergren and hematocrit values were obtained with the method of Wintrobe in duplicate tests (32). The coagulation times were run at room temperature within 21 to 25 degrees C. Each cubic centimeter of blood tested in duplicates using pyrex tubes 10 by 100 millimeters. Platelet counts were made according to the Copley Robb method (13, 14) 0.5 per cent solution of brilliant cresyl blue (national aniline NV 27) being used (9). Clot retraction was tested according to Aggeler, Lucas, and Hamlin (2) in duplicate tests. A correction was used for the clot volume in this test, since we had observed in some human blood a rather high red blood cell sediment following the incubation of the blood coagulum. This volume of sedimented cells is to be added to the volume of the coagulum for the determination of the proper serum volume. Furthermore, for determining the extracorporeal volume, the coagulum and

the sediment are taken as the volume from which the hematocrit volume is subtracted, thus giving a more accurate extracorporeal volume. This correction may not be practical in all instances, however, it is necessary in all cases where a markedly increased sedimentation rate takes place.

The clot firmness was determined according to the method of Lalich and Copley (20). All clot firmness tubes were run in triplicate tests. Since tissue juice affects the coagulation time and firmness of the coagulum (20) blood was secured in a separate syringe for these tests. The same needle, placed *in situ* was used for all blood withdrawals.

The alcohol test with serum was made with a slight modification as previously described by Copley (8). Two-tenths cubic centimeter of 80 per cent ethyl alcohol was added to 0.2 cubic centimeter of native serum well mixed for incubation at 37 degrees C. The degree of gelation was recorded after 5 minutes' incubation time. The appearance of filaria was observed on a wet slide in citrated blood.

RESULTS

I Clinical observations A Splenectomy

Dog 844 and dog 814 had their spleens removed. The postoperative course of both animals was uncomplicated. Dog 814 developed a postoperative secondary anemia this however subsided on the 31st postoperative day.

B Autotransplantation of spleen

Dog 818. In this animal the spleen was removed and transplanted to the left inguinal region. The splenic artery and vein were anastomosed to the femoral artery and vein respectively.

On the first postoperative day the spleen was found enlarged and firm on palpation. It occupied the lower half of the abdominal cavity. On the second postoperative day the animal was found dead in the cage. On gross examination the organs of the thorax appeared to be normal. Gross examination of the abdomen revealed the spleen to occupy the lower portion of the peritoneal cavity. The spleen was firm and markedly enlarged. It measured 30 centimeters along its axis, 2.5 centimeters in thickness and 11.5 centimeters across its broadest points weighing 300 grams. On cut section the organ emitted blood freely in large amounts. The anastomoses of the femoral and splenic vessels were found to be patent with no evidence of thrombosis. Postmortem diagnosis splenomegaly.

Dog 846. In this animal the spleen was left attached to its usual pedicle with the exception of the

splenic vein which was anastomosed to the middle colic vein.

On the first postoperative day the spleen was palpable. The animal and the wound were in good condition. On the second postoperative day the animal was found dead in the cage. On gross examination at autopsy the left lungs were noncrepitant and infiltrated while the right lungs appeared normal. Heart and greater vessels did not show any gross pathologic changes. Examination of the abdomen revealed an enlarged spleen measuring 30.5 by 9 by 2.5 centimeters and weighing 500 grams. The anastomosis of the splenic vein and middle colic vein was found to be patent and did not show thrombi. The remaining organs of the abdomen did not show pathologic changes. Postmortem diagnosis bronchopneumonia splenomegaly.

Dog 67. In this animal the spleen was removed from its usual pedicle and transplanted to the left inguinal region. The splenic artery and splenic vein were anastomosed to the femoral artery and vein respectively.

On the first postoperative day the animal was found in shock and was given an infusion of 300 cubic centimeters of 10 per cent glucose in saline. Approximately 300 cubic centimeters of sanguineous fluid was evacuated from the abdominal cavity. The spleen was palpated and found to occupy both lower quadrants.

On the second postoperative day the animal was found dead in the cage. The thorax and abdomen were examined on autopsy. Approximately 75 cubic centimeters of serosanguineous fluid was contained in the right chest. The right lungs appeared to show infiltration indicating lobar pneumonia. The left lung appeared to be normal on gross examination. No gross pathologic changes were in the heart and greater vessels. Examination of the abdomen revealed the spleen markedly enlarged occupying the lower abdomen and displacing the other viscera. It measured 30 by 7 by 1.5 centimeters and was firm and congested. The anastomoses of the femoral and splenic vessels were patent and it appeared that they were functioning prior to death. The remaining abdominal organs did not exhibit pathologic changes. Postmortem diagnosis splenomegaly.

Dog 840. The spleen was taken from its pedicle and transplanted to the right inguinal region, the right femoral artery and vein being used as the source of blood supply. This animal survived the operation and was maintained for 31 days. An exploration was done on the 27th postoperative day at which time the spleen was found to be two-thirds its original size. The splenic vessels were palpable and pulsating indicating patency of the anastomoses.

It might be stated at this point that at the time of transplantation, directly following the anastomosis 0.2 cubic centimeter of a 1,000 adrenalin chloride was injected into the substance of the spleen to reduce enlargement and possibly any future development of splenomegaly.

C Homotransplantation of second spleen.
In two dogs, No. 845 and No. 849, a second spleen was incorporated. These spleens were transplanted to the femoral region of the recipient.

Dog 845. The spleen of dog 844 was implanted in dog 845 in the left inguinal region anastomosing the femoral vessels to the splenic vessels. This animal had a stormy postoperative course and expired on the second day after operation. At autopsy the spleen was found markedly engorged with blood and the peritoneal cavity was filled with serosanguineous liquid. Postmortem diagnosis peritonitis, splenomegaly.

Dog 849. The spleen of dog 814 was transplanted into the left inguinal region. The femoral vessels were employed to anastomose to the splenic vessels. This animal, like dog 845, had a stormy course and died suddenly on the second postoperative day. At autopsy the spleen was found to be engorged with blood and the peritoneal cavity was filled with serosanguineous fluid. It could not be determined whether the anastomoses were patent. Postmortem diagnosis Peritonitis splenomegaly.

II Hematologic findings. Tables I and II give data obtained in 16 healthy dogs. Twenty comparisons of hematologic findings are made. The red blood count varies from 6.21 to 8.47 millions. The hemoglobin varies between 12.5 to 18 grams per 100 cubic centimeters. The hematocrit ranges from 39 to 61 per cent. The erythrocyte sedimentation rate (Wintrobe) after 60 minutes was found to be zero in 10 tests, whereas the remaining ones showed variations from 2 to 21 millimeters. The coagulation time at 21 to 25 degrees C. varied from 1.5 to 6 minutes. Platelet counts ranged from 200,000 to 360,000. All tests for clot retraction showed differences between 36 and 59 per cent serum volume. The extracorporeal volume was zero in 3 tests and varied from 3 to 22 per cent in the remaining tests. The clot firmness was found in 14 tests to be between 65 and 145 millimeters mercury and in the remaining 6 tests ranged between 160 and 395 millimeters mercury. The white blood count differed from 7,000 to 16,400. This variation was found at 2 days interval in dog 845. The differential white count differed considerably. Nonsegment forms differed from 1 to 12 per cent in 19 tests and in one dog 33 per cent were found. Lymphocytes ranged from 13 to 61 per cent and monocytes were found in 15

TABLE I—TWENTY COMPARISONS OF VARIOUS HEMATOLOGIC FINDINGS OBTAINED FROM 16 HEALTHY DOGS

Dog number	Hemoglobin gm.	Hematocrit percent	Sedimentation Rate 60 min. mm.	Alcogel test 5 min. 37° C.	Coagulation time in min. (-15° C.)	Platelet count in thousands	Clot retraction		Clot firmness mm Hg	Filaria

tests amounting to 1 to 9 per cent. In 11 tests no eosinophils were counted and in 6 tests they ranged from 1 to 3 per cent and in the 3 remaining they were 13 to 16 per cent. No basophils were found in 17 tests, the 3 remaining had 1 to 3 per cent. Nine nucleated red cells were found in dog 849 which also exhibited anisocytosis poikilocytosis, polychromatophilia, and target cells. No target cells were seen in the other dogs. Anisocytosis was found in one healthy dog and polychromatophilia in 2 dogs. The serum alcogel test was negative at 5 minute readings. Filaria (*Dirofilaria immitis*) have been observed in only one dog. In this connection it may be of interest to present the occurrence of filaria in 2 cases in another series of 24 dogs.

Table III exhibits comparative hematologic findings previous to and following splenectomy. In dog 844 these findings were from samples obtained 1 day before and prior to operation and on the 3rd and 19th postoperative days. In dog 814 a complete series of tests was run shortly before operation and up to the 31st day on 5 different postoperative days. Postoperatively dog 814 developed a secondary anemia which however on the 31st day appeared to have subsided. In this animal target cells and Howell Jolly bodies were observed following splenectomy. In dog 844 no target cells were seen and Howell Jolly bodies appeared in the control. Nucleated cells appeared only in this animal following operation. There is a trend of lymphopenia postopera-

tively in dog 814. The platelet count does not alter and is within normal limits. The coagulation times of 100 per cent whole blood do not change significantly. The sedimentation rate is increased in dog 814 following operation and approaches its preoperative value on the 31st day. The clot retraction is present following operation in both dogs. On the 3rd and 4th postoperative days, however, there is a slight increase of the extracorporeal volume of the clot. The only abnormal finding in both dogs postoperatively is the increased clot firmness. This increased clot firmness persists for several weeks and exhibits in dog 814 a gradual decrease which, however, is still well above the preoperative values on the 31st postoperative day.

Table IV exhibits a complete series of hematologic findings in 2 dogs with autotransplantation of the spleen to the femoral artery and

vein and in 1 dog transplantation of the splenic vein to the middle colic vein. In all dogs there was a slight fall in red cell count, hemoglobin and hematocrit. Howell-Jolly bodies were seen also in the controls of dog 67 and dog 846. Target cells could be observed in dogs 840 and 846 and nucleated red cells were seen in dog 67 following spleen transplantation. The sedimentation rate is increased on the 2nd and 4th postoperative days, whereas unchanged on the 1st postoperative day. The coagulation time of 100 per cent whole blood is within normal limits. The platelet count was unchanged throughout. Clot retraction was present in all instances. In dog 67 there was an increase of the clot volume, signifying decrease in serum volume and an increase of the extracorporeal volume of the clot. In all instances there was a slight fall in lymphocytes postoperatively within the 1st and 4th

temperatures for a few hours, and more rapidly at colder temperatures. This makes it necessary to place the flask of gelatin in hot water for ten or fifteen minutes just before starting the infusion, unless the material has been previously kept in a warm cabinet. Some difficulty would be encountered in using this type of gelatin under any conditions where the environmental temperature is below 65 degrees F but in ordinary hospital practice gelation is not a troublesome problem.

Another shortcoming of gelatin is its relatively low nutritive value, it being deficient in at least four of the amino acids essential for the composition of a "complete" protein. There is evidence that gelatin may be utilized as protein in the body economy if given in conjunction with other complete proteins, but for meeting the nutritional requirements of surgical patients, gelatin is not equivalent to plasma, whole blood, or intravenous protein hydrolysates. It seems possible that this limitation of gelatin might be overcome by adding to it sufficient amounts of the amino acids in which it is deficient, but this has not yet been accomplished on a commercially practical basis.

A minor troublesome property of gelatin is its tendency to cause erythrocyte rouleaux formation ("pseudo-agglutination") with a consequent accelerating effect on the sedimentation rate. There is no evidence that intravascular rouleaux formation is of any physiological consequence, and the only re-

spect in which it becomes of importance is in the interpretation of blood grouping and cross-matching reactions of patients whose blood contains gelatin. It has been pointed out that the microscopic appearance of the rouleaux is markedly different from that of agglutinated erythrocytes, but the technician who is not trained to recognize the difference may experience difficulty in making the correct interpretation. Fortunately the production of rouleaux is inhibited in the presence of 1 per cent glycine, and a technique has been described for eliminating pseudoagglutination as a source of confusion.

The distribution and clinical use of gelatin has thus far been limited because of the availability of large quantities of surplus Red Cross plasma, and because of the recent emphasis on the need for whole blood in the replacement therapy of hemorrhagic shock and burns. However gelatin has earned a useful position as a substitute for plasma under conditions where maintenance of plasma volume is the principal requirement, and it should find important future applications in civil and military surgery particularly under conditions where plasma is not readily available. After gelatin has been used to maintain circulatory dynamics in accidental or operative trauma, or burns, any significant deficit of red cell mass should be compensated by transfusions of whole blood, just as is required with plasma itself.

JOHN S. LOCKWOOD.

DISCUSSION

1. *Hypersplenism.* There are numerous reports and observations on splenomegaly in the literature in connection with various diseases of different nature signifying an enlarged spleen.

Ordinarily the spleen is only increased in conditions with splenomegaly which however are not physiologic but the result of pathologic changes. In introducing a second spleen or several spleens the part of the circu-

lation to which the organ is connected may also be significant. It might well be that the normal site of the spleen in the circulatory system is of functional significance. In spleen transplantation there are considerable technical difficulties to overcome, and it is obvious that to certain parts of the circulation a spleen could not be attached.

The term "hypersplenism" has been used in the literature with various meanings, e.g. the presence of accessory spleens, "hyperactivity"

TABLE V—PLATELET COUNTS FOLLOWING SPLENECTOMY HOMOTRANSPLANTATION OF SECOND SPLEEN TRANSPLANTATION OF SPLENIC VEIN AND AUTOTRANSPLANTATION OF SPLEEN IN DOGS

of the spleen or increased hemolytic spleen action. Nothing is known about the physiologic functions of the spleen in a 'hyperactive state. Singer, Miller and Dameshek speculated that such hyperactivity may concern the total of splenic functions or selectively' be limited to one function.

Accessory spleens are only detectable following laparotomy and careful search. It is not known whether their single or multiple occurrences amplify physiologic functions of the spleen whatever they may be. Curtis and Movitz reviewed recently the literature on accessory spleens in humans. Their own series of 178 patients represented an incidence of 31 per cent throughout various splenic disease and age groups. They made the observation that the unremoved accessory spleen may cause a recurrence of either primary thrombocytopenic purpura or congenital hemolytic icterus. Significant is their finding that persistent recovery from a recurrence after splen

ectomy was observed following the surgical removal of accessory spleens at a second operation in a case of congenital hemolytic icterus.

There is still another occurrence of multiple accessory spleens' and as many as 400 have been counted in one single patient. They were found scattered throughout the peritoneal lining and were considered as transplants resulting from traumatic rupture of the spleen and seeding of the peritoneum with splenic fragments. They often developed subsequent to splenectomy for traumatic rupture of the spleen. Buchbinder and Lipkoff reviewed the literature of this condition for which they introduced the term *splenosis*. The actual frequency of occurrence of splenosis is not known according to Curtis and Movitz. These authors stress the clinical significance of accidental production of splenosis during a splenectomy for primary splenic disease. It will have to be shown whether the experimental production of splenosis in normal nonsplenec-

tomized animals would result in certain increased physiologic splenic functions.

2 *Spleen transplantation.* The transplantation of the spleen has been attempted by several investigators. The usual approach was transplantation of autogenous and homologous spleen or spleen tissue without anastomosis of the splenic artery and splenic vein to the circulation. Such autotransplantations of splenic tissue were successful with some investigators (24). The other approach of transplanting the spleen to the circulatory system has been made by Carrel (6, 7) who employed his suture method for vessel anastomosis. Carrel (7) concluded that the section of the vessels of the spleen of a dog, the section of their nerves, the suspension of their circulation for about 50 minutes and their extirpation and perfusion with Locke's solution do not modify their functions and their anatomical condition when they are replanted on the same animal. Our investigations, using the nonsuture method of Blakemore Lord and Stefkó, have been successful inasmuch as one of the 4 dogs with autotransplants survived and was observed for 31 days. The 2 dogs in which a second spleen was transplanted lived for only 2 days.

The cause of the death of the 5 spleen transplanted animals may be due either to bronchopneumonia, peritonitis or to intra-splenic hemorrhage. It is not clear whether the animals hemorrhaged most of their blood into the transplanted spleen and that they died of hemorrhagic shock. The possibility exists that the spleen tumor may have compressed the aorta, vena cava or other vital vessels or organs. All these giant spleens were signified by the presence of large quantities of blood. There can be no doubt that they originated from the influx of blood.

In one animal only splenomegaly and no other pathologic changes were observed at autopsy. At least in this animal, it appears to be certain that the cause of death was due to the enlarged spleen. Whether the hemorrhage into the spleen as such or the sequelae due to the splenomegaly were primarily responsible for the death of the animals cannot be decided. It is quite possible that these animals died of shock following hemorrhage into the spleen.

In order to eliminate splenomegaly the spleen of one animal was injected with adrenalin shortly following transplantation. This resulted in rather immediate contraction of the slightly enlarged spleen. It is of interest to note that apparently this one single adrenalin injection inhibited any future development of splenomegaly. This animal survived, and on exploratory laparotomy on the 16th postoperative day we observed a slight decrease in the size of the spleen from its original size previous to splenectomy thus corroborating the palpatory findings obtained on any of the postoperative days previously. The phenomenon of splenomegaly as found on 5 occasions following autotransplantation of the spleen in 3 dogs or following homotransplantation in 2 dogs merits further study.

Loeb recently reviewed the literature on the interaction of the "individuality differentials" of host and transplant. He designates as individuality differential a particular characteristic which is common to all the various tissues, organs, and body fluids of an individual and distinguished it from another. Loeb finds that transplantations by blood vessel anastomosis are of special interest because they make possible a separation of the effects of the body fluids on transplanted tissues from those of the host cells. Loeb summarized the observations of Carrel and of Guthrie who, in employing blood vessel anastomosis found that not only autotransplantation but also homotransplantation of kidney, thyroid, adrenal, and ovary succeeded. It may well be that homotransplantation of organs can be successful only in using vessel anastomosis instead of simple grafting.

3 *Hematologic observations.* a. *Control dogs.* It is of interest to note the wide variation of red and white blood counts and in a few cases a marked eosinophilia. The only case of filariasis in dog 845 may have affected the differential count however this cannot be stated with certainty. There is also marked variation in hemoglobin and hematocrit values. Red cell sedimentation is either present or absent.

The coagulation times are within normal range. At the time these investigations were performed, the blood saline coagulation time

test of Copley and Houlihan (11) was not developed and changes in blood coagulability of healthy dogs could therefore not be correlated to any of the other hematologic findings. Meanwhile such changes in coagulability have been shown in animals of various species (12).

The platelet count with the Copley Robb method is well within normal range as established by these workers (14). It should be emphasized that stains in proper concentration should be employed in making the count. In the original paper of Copley and Robb (13, 14) a much lower concentration of brilliant cresyl blue stain was given. This employed stain had a higher dye content and was of foreign source. Meyer (25) found that with the originally recommended concentration of 0.2 per cent dye the platelets would not take the stain. We could corroborate his observations in employing brilliant cresyl blue N.V. 27. In making a 0.5 per cent concentration of this dye we found satisfactory staining of platelets (9).

According to the method of Aggeler, Lucia, and Hamlin the extracorporeal volume in most cases showed only small values. The necessity for introducing the correction to the extracorporeal volume has been discussed in the section of methods. These corrections were insignificant in all control dogs.

The clot firmness of Lalich and Copley (20) was in the majority of instances below 180 millimeters of mercury viscometers of internal diameters of 10 millimeters in the wide portion and 3 millimeters in the narrow portion being used. Repeated tests on different days in the 3 dogs 832, 844, and 845 showed close agreement. In only 3 dogs the clot firmness in these tubes was 220 millimeters of mercury or more. This test is a measure of the hemostatic function of the blood and except in hemophilia has not yet found clinical application.

The alcohol reaction of serum was found negative in all dogs. This test belongs to the group of lability reactions and has been found not to occur in healthy humans. There is no correlation of this test to the sedimentation rate. The findings with the alcohol test in healthy dogs are the first to be reported.

The observed wide variations in data obtained with certain hematologic tests in different dogs or at times in the same animal on different days (see Table II, Dog 845) suggest that control values should preferably always be run in the same animal previous to operative procedures. This practice promises to better establish any hematologic changes brought about by surgical manipulations.

b Splenectomized dogs One splenectomized dog exhibited definitely secondary anemia. This phenomenon has been first observed in dogs by Pearce. The other dog showed only insignificant decrease in hemoglobin and hematocrit values on the 19th day. Such a trend of anemia may better have been brought about in case more determinations would have been made. Any blood loss due to the operation was minimal and could not account for the anemia which developed in dog 814. The hematopoietic activity postoperatively in dog 814 runs parallel with the hemoglobin, red blood cells, and hematocrit values and returns to approximately the preoperative values on the 31st day.

Singer, Miller, and Dameshek observed Howell-Jolly bodies as a constant finding in 19 human subjects who were splenectomized for various clinical conditions. Roth was the first to describe Howell-Jolly bodies after splenectomy in man. Red cells containing these bodies were observed by Jolly to occur normally in the blood of young mammals. We found them occasionally in adult dogs preoperatively (Tables III and IV). However they were always present following splenectomy and spleen transplantation. Target cells were found by Singer and associates in most cases following splenectomy. We observed these cells in 1 splenectomized and 2 spleen transplanted dogs.

The claim that the platelet count is increased following splenectomy has not been substantiated after splenectomy of normal dogs. The frequent occurrence of an increased platelet count following splenectomy in certain pathologic conditions with splenomegaly in humans is frequently misinterpreted to mean that any splenectomy, even in healthy animals and humans, is followed by an increase in the platelet count. There have been

several investigators who claimed that thrombocytosis occurred postoperatively in various surgical conditions. A discussion of these claims is given in a recent study by Adams. We cannot enter into a discussion of the controversy pertaining to postoperative thrombocytosis because we are only concerned here with the observations of thrombocytosis following splenectomy in healthy animals.

The effect of splenectomy on the platelet count was summarized by Krumbhaar. He states that the rise in platelet count following splenectomy was found both experimentally and clinically though the evidence varies as to the duration and cause of the increase. In Krumbhaar's own experiments on dogs he found increased counts from 50 to 200 per cent higher after 3 to 12 months at the end of the observation than before operation. Immediately following the operation there was a considerable rise, but after a drop toward normal a second rise was observed which was lasting. He speculates that the postsplenectomy thrombocytosis is the result of both decreased thrombocytolysis and decreased inhibition of platelet formation. It should be noted that Loesch Witts, and Zimmermann made several studies of platelet counts before and after operation in 3 dogs. In 2 dogs they ligated the splenic veins and they splenectomized a third dog. There are marked fluctuations in their platelet counts.

In our experiences, we have found at times great fluctuations in platelet counts in healthy dogs on various days, i.e. increases up to 91 per cent, otherwise the values were usually constant over a long period of time. It is not understood to what mechanisms such fluctuations are due. One may find similar objections if one analyzes the detailed data of other workers who have made platelet counts in experimental animals or in healthy humans. Although it is not possible for us to discuss the literature on platelet counts, we wish to emphasize that platelet counts should be well controlled. In our appraisal there are few reliable methods for making platelet counts. Thus perhaps most papers giving values for them rather confuse the actual facts and do not contribute to a better understanding of the number of platelets in the circulating blood.

Wollstein and Kreidel reported platelet counts in children on whom splenectomy was performed. They found that in 3 cases of traumatic rupture of the spleen, in 20 cases of rheumatic disease, and in 4 cases of congenital, hemolytic icterus, there was no immediate increase after the operation but an increase appeared toward the middle or end of the first week. Shore and Kreidel reviewed the literature on 210 unselected surgical cases exclusive of splenectomies by 3 groups of observers. A marked rise of platelets was manifested from the sixth to the fourteenth postoperative day. However a similar rise was found in 3 traumatic cases without operation. Wollstein and Kreidel did not find any appreciable rise in the platelet count in 4 children following operations other than splenectomy.

We do not need to question the results of platelet counts so consistently obtained in certain clinical conditions in man with splenomegaly which have shown marked decreases in the count previous to operation and a return to normal limits following splenectomy. We believe platelet count increase is true only in such pathologic conditions and that the increase in platelet counts postoperatively following the removal of the spleen in healthy subjects will still have to be proved. Binet and Kaplan did splenectomies in 3 dogs. Platelet counts before and after operation were the same in one dog slightly decreased in a second dog and moderately increased in a third dog following splenectomy. Platelet counts can be very demonstrative, although they should be reliably recorded with improved methods of counting the platelets.

The occurrence of accessory spleens should be considered in studying the effect of splenectomy on the platelet count. To our knowledge, no importance has been placed on this phase of the problem. Such accessory spleens may substitute for any deficiency following the removal of the spleen. We often found in autopsies and during laparotomies accessory spleens in dogs however none was observed in our 2 splenectomized animals.

c Splenic transplanted dogs The comparative series of hematologic tests which were completed in 3 dogs show similar results as

obtained in dogs following splenectomy. There is a decrease in red cell count, hematocrit and hemoglobin in dogs 67 and 840. The occurrence of Howell Jolly bodies and target cells have been discussed in the preceding section. Findings on the first postoperative day in dog 846 with anastomosis of the splenic vein to the middle colic vein suggest a trend toward anemia. In all instances there is a trend of lymphopenia within 4 days postoperatively. This was also indicated in the splenectomized animals. It is of interest that the sedimentation rate does not increase before the second postoperative day, a finding which we also observed in the 2 dogs in which a second spleen was transplanted. In these homotransplanted dogs there was no change in the sedimentation rate on the first postoperative day. No tests could be made on the second postoperative day because the dogs had died.

A comparison of the platelet counts showed no significant change in any of the 6 spleen transplants. These findings are of additional interest since 3 dogs (846, 818 and 67) exhibited splenomegaly already on the first postoperative day. The presence of extremely enlarged spleens together with normal platelet counts would indicate that splenomegaly *per se* is not always associated with a decrease in the platelet count. It seems to us that possibly specific pathologic conditions in certain diseases with splenomegaly account for the decrease in the number of platelets in the circulating blood. It is possible that this decrease of circulating platelets originates with pathologic changes of the enlarged spleen.

Our 5 cases with experimentally produced splenomegaly were apparently due to hemorrhage into the spleen. It is not known yet whether these giant spleens developed so rapidly due to blockage of the venous return or other disturbances.

d. Observations on clot firmness. There are no other striking differences in the results obtained with various hematologic tests following operation with the exception of the clot firmness test. The clot firmness was increased in all instances of spleen transplantation and showed similar findings as in the 2 splenectomized dogs. This interesting observation however is not specific to severance of or injury

to the splenic vessels, but has been observed in 3 other dogs following laparotomies. Whether the animal has the ability to increase the hemostatic function of the blood following abdominal or other major operation, as indicated by these increased clot firmness values should be kept open for further investigation.

The mechanism of clot firmness is not as yet understood. There is no correlation between clot retraction and clot firmness as has been shown in model tests by Copley (10). These observations amplify the findings of Lahch and Copley (20) who found decreased or absent clot firmness with hemophilic blood. It is well known that blood coagula from hemophilic patients exhibit syneresis. The clot firmness test may prove to be a valuable clinical aid for estimating the hemostatic function of the blood. Moreover it invites a study whether patients with certain hemorrhagic disorders would also show an increase in clot firmness following splenectomy or other operations and whether the deficiency of a certain substance or substances would account for the impaired hemostatic function of the blood. Hemostasis is not identical with blood clotting (15, 21, 27). The latter only comprises the different processes which lead to the clotting of blood *in vivo*. Arrest of hemorrhage or hemostasis depends upon other factors which reside both in the blood and the site of the traumatized tissue or the damaged blood vessels.

SUMMARY

1. Twenty series of comparative hematologic tests have been made in 16 healthy mongrel dogs. Each series consisted of red blood count and its differential smear, hemoglobin, hematocrit, total and differential white blood count, platelet count, sedimentation rate, serum albumin, differential clot retraction, coagulation time of 100 per cent native blood, clot firmness and search for filaria. Data obtained with these series of tests are presented and discussed.

2. Eight animals were subjected to the following operative procedures: (a) splenectomy, (b) reimplantation of the animal's spleen to a different part of the circulation, and (c) implantation of a second spleen to the general circulation.

3 Two dogs were splenectomized and complete series of hematologic findings were obtained preoperatively and on different days postoperatively

4. In 3 dogs autotransplants of the spleen were made to the femoral artery and femoral vein by means of the nonsuture method with vitallium tubes. In 1 animal the splenic vein was transplanted to the middle colic vein. In 2 dogs a second spleen was transplanted to the femoral artery and femoral vein. The operative procedures are presented

5 Two dogs died with peritonitis on the second postoperative day following homotransplantations of a second spleen. Three animals with autotransplants of the spleen died on the second postoperative day. They all exhibited splenomegaly and each spleen had a weight of about 500 grams. Two animals with autotransplants had one-aided pneumonia, whereas a third animal did not exhibit any pathologic changes other than the splenomegaly. It is believed that all 3 of the dogs died of hemorrhage into the transplanted spleen.

6 One dog with autotransplantation of the spleen survived. The spleen substance of this dog was injected with adrenaline hydrochloride at the time of the completed anastomosis. No splenomegaly developed in this animal. On exploratory laparotomy on the 27th day the spleen was about two-thirds of its original size. Good pulsation of the splenic artery through out the anastomosis and good venous return of the femoral vein were found. It is not clear whether the one single injection of adrenalin was responsible to counteract the development of splenomegaly and whether its absence permitted the survival of the animal.

7 Complete series of hematologic findings are presented from 2 dogs following autotransplantation of the spleen and anastomosis of the splenic vein to the middle colic vein. The hematologic findings are similar to those which were obtained in the two splenectomized animals.

8. Clot firmness which signifies increased hemostatic function of the blood was always found increased following operation. This phenomenon was a constant finding following laparotomy in 3 other abdominal operations

in dogs, and is not considered to be in direct connection with the spleen function.

9 Platelet counts have been obtained preoperatively and postoperatively in 2 dogs with homotransplants of a second spleen, and in the 4 dogs with autotransplants of the spleen. No significant change in the platelet count was observed in the peripheral blood of these animals as also was the case in the two splenectomized dogs. It is emphasized that splenomegaly *per se* may not affect the platelet count.

10. The principle of introducing one or multiple spleens into various parts of the circulation is discussed as a method to advance our knowledge of the functions of the spleen. The direct attachment of a second spleen to the circulatory system is proposed as a method for increasing physiologically active splenic tissue.

11 Hypersplenism with regard to its various designations and the significance of accessory spleens are discussed.

THE CHEMOTHERAPY OF CANCER

AFTER long desire a beginning has been made recently in the chemical treatment of advanced cancer and in fact results of no small magnitude have been achieved since 1941. The desire to solve a problem in itself is insufficient to do it. In good science the problem must be conceived clearly and the simplest possible approach devised, bearing in mind that the greater the number of variables the greater the number of equations are required. The advances in medicine are directly related to the development of the other sciences which in our age has been stupendous.

It is now possible to see practical methods of approach to the difficult problem of disseminated cancer and the concepts seem to be easier to define than they were a decade ago. Several inhibiting agents have been found which are more or less effective in the treat-

ment of the tumors of man and animals. The advances have concerned a few specific tumors rather than cancer as a whole, and here the development resembles the history of treatment of infectious diseases: cure of infection did not evolve as such but over the years treatments were gradually devised for specific and particular infectious diseases.

Work with pure chemicals has been the most profitable: crude extracts and laboratory soups have yielded only slight dividends. Such a great number of pure compounds are available for systematic investigation that the chance of success from an erratic procedure empirically developed is too small to interest most professional investigators. In studying normal structures, one is also contributing to the foundation of the study of cancer: the systematic investigation of disease is possible only in proportion to what is known about the function of normal organs.

No doubt the greatest handicap in the development of cancer treatments has been the lack of things to measure: time is of the essence in the evaluation of putative therapeutic modifications and cancer is frequently so indolent and diffuse as to defy quick and precise measurement. Always one is faced with the fear that a little improvement may escape detection and a valuable lead thus be overlooked. The only rapid indicators of neoplastic activity now available in man concern tumors of the blood forming organs and cancer of the prostate. In neoplasms of hemopoietic tissue the circulating cellular elements are available for quantitative study and in prostatic cancer the serum phosphatases^{1,2} provide rapid and

DISCOVERY PAINS

ESTHER H. VINCENT Evanston Illinois

IN contemplating the adventures of Christopher Columbus, we experience all the delightful thrills of patriotism mystery stories and bingo. As children we bounced our balls to the rhythm of

Columbus sailed the ocean blue
In the year of fourteen ninety two |

And, as grown-ups, we find in these lines just about all we can be sure of in connection with the Admiral of the Ocean Sea. Like the discovery of anesthesia the discovery of America may be said to have a three or four way stretch. Columbus must share honors with Vikings, French fishermen, and possible other early navigators who were afflicted with secrecy. That the 1492 voyage was not Columbus's first Caribbean tour has been suspected. Doubts as to the virginity of his experience as a discoverer have arisen, but since publicity determines fame, the 1492 escapade is the one that counts.

According to the chroniclers, our hero was born anywhere from 1436 to 1451. That he was a native of Genoa is a moot point. He said he came from there and in a codicil to his will, he left a sum of money for the building and endowment of a Genoese hospital for the poor. Nevertheless, he was never known to speak or write Italian, and of the 124 Colombos living in Genoa in the fifteenth century not a single family claimed relationship with the great discoverer. He seems deliberately to have veiled his early life, and even disguised his name in a cabalistic signature of which nothing but "Christ Bearer" can be made out. So when we gaze reverently at the urchins playing about the doorway of number 37 Vico dritto del Ponticello Genoa, we cannot be too sure of visualizing little Cristoforo.

Present-day tales of Columbus trace their descent from his own notes and diaries, and from the biographies of Ferdinand and Columbus, his natural

From the Archibald Church Library Northwestern University Medical School.

son and of Bartolomé de Las Casas, first priest ordained in the New World. These records, however, are as misty and windy as the sea over which the Santa Maria sailed. The Admiral himself apparently had acquired the habit of mixing fact with wishful thinking certainties with expectations. It was not until the eighteenth century that the lamp of fame illuminated the Columbian legend. By that time it was difficult to tell the false from the true the forged from the original the fairy tales from the realities.

Columbus appeared on the scene at the time when the shadow of Islam was retreating before the rising sun of royal Spanish Christianity when the dawn of the Renaissance was beginning to dispel the gloom of the Middle Ages. Story has it that he was the son of a Genoese weaver of substantial means, that he was the eldest of a family of three sons and one daughter that he had blue gray eyes and reddish hair (early becoming gray) a hawk nose a thin, straight mouth and a tall muscular well proportioned figure. He is supposed to have attended the University of Pavia to have been trained as a weaver, and to have had some sailing experience, possibly sprinkled with dash of piracy. He may have reached England and there are rumors of Iceland. It was in Lisbon that he married Felipa Moniz Perestrelo daughter of an aristocratic Italian navigator and explorer to whose charts and nautical instrument Columbus fell heir. It was there too, that he is said to have entered into exciting scientific correspondence with cosmographer Toscanelli brilliant son of a Florentine physician.

Columbus spent about ten years in Portugal making and selling maps, studying and dreaming maps, and waving maps around in the face of John II. John was sympathetic to the waving but his Council of Geographers was not. All that Columbus had to show for his Portuguese trial was a broken hope and his son, Diego. Finally Felipa having died, the would-be discoverer too, Diego by the hand and set out for Spain. There

elegant indices of the activity of the cancer. Obviously the development of a chemical method for the study of the activity of any other cancer will be of first class importance.

At this time it is only possible to notice those chemical methods of treatment which seem to have been well established. They may be divided into 3 groups according to their action.

1 *Necrotizing agents* It has long been known that certain bacterial products when administered parenterally to creatures bearing sarcomas produce severe hemorrhage in the tumors within a few hours with subsequent necrosis of the affected area of the neoplasm. The separation of the hemorrhage producing agent in a culture of *Serratia marcescens* (*Bacillus prodigiosus*) from toxic and inert contaminants has been accomplished by Shear and co-workers in a brilliant series of investigations^{3,4} it has been found to be a polysaccharide which is active in very small amount. Unfortunately in most cases the necrosis of the tumor is not complete and while certain tumors regress some of the tumor usually remains viable. From experiences with other agents, it is not considered necessary nor desirable that an anticancerous agent produce instant and massive necrosis to be effective.

2 *Competitive inhibition and the essential foodstuffs* It has been found in cancer of the prostate that androgen is often an essential item for the nutrition of the malignant cell; the tumors grow vigorously when androgen is administered in appropriate dosage and the cells tend to wither when the androgen supply is removed (orchietomy) or estrogen is administered. Estrogen was the first agent of known chemical composition, aside from radioactive chemicals, which ameliorated wide

spread cancer and was the first substance known which affected cancer adversely when fed by mouth. Both estrogen and orchietomy are in effect chemotherapeutic agents although nonspecific ones.

Heilman and Kendall⁵ found that the compound E of Kendall derived from the adrenal cortex caused massive involution of lymphosarcomas in female and young male mice. The work of Abraham White and Dougherty⁶ has demonstrated a relationship of the adrenal cortex to lymphocytes in that adrenal stimulation causes a decreased activity of lymphoid tissue. The damaging effects of 11-dehydro-17 hydroxycorticosterone on lymphoma is in line with these biochemical observations.

The theory of competitive inhibition arose from the work of Wood and Fildes wherein sulfonamides in proper concentrations were found to eliminate the effectiveness of *p*-aminobenzoic acid a substance essential for the growth of certain bacteria.

3 *Nuclear damage* It has long been established that irradiation damages cells, and because of the frequency of induced mutations as well as much other evidence the principal effect of irradiation is believed to be on the nucleic acids of the cell nucleus. The radioactive isotopes with a short period of decay constitute a useful method of presenting soluble radioactive chemicals to the organism as a whole. Radioactive phosphorus has great value in chronic lymphatic and myelogenous leukemias⁷ and is probably the best therapeutic agent which is now available for polycythemia vera.⁸

The nitrogen mustards (β chloroethyl amines) have presented an interesting devel-

opment in the cancer problem. Following the demonstration of Lushbaugh that these chemicals caused a lowering of the lymphocyte count of rabbits they have been studied systematically from a biochemical standpoint.⁹ The nitrogen mustards have been used in clinical patients in the treatment of Hodgkin's disease, and it has been found that regression^{10,11} sometimes occurs after their use. The mustards are the only agents known which can produce mutations chemically¹² an effect which hitherto has only been produced by radiant energy.

Still another agent capable of producing regressions in cancer is ethyl carbamate (urethane) which has produced regression of transplantable carcinoma in mice¹³ as well as in human leukemia.¹⁴ Urethane has long been known to delay cell division¹⁵ without great interference with respiration, but the present interest in this substance in cancer research is due to the efforts of Haddow. It has recently been shown that urethane is able to reduce the growth of human prostatic cancer¹⁶ and notably in patients where a relapse has occurred after hormonal treatment with orchiectomy and estrogen: the drug is not antiandrogenic and so constitutes a new principle in the treatment of advanced prostatic cancer acting by pycnosis. The drug is toxic and great care must be exercised in its administration however it is another shot in the therapeutic locker.

MEDICAL ASPECTS OF THE LEWIS AND CLARK EXPEDITION (1804-1806)

O LARSELL, Portland, Oregon

THE Lewis and Clark Expedition (1804-1806) sent by President Thomas Jefferson to the Columbia River has had so important an effect on the subsequent history of the Pacific Northwest that all aspects of this epochal journey are of great interest. As leader of the Expedition President Jefferson selected Captain Meriwether Lewis (1774-1809) of the United States Infantry. Lewis was an educated man with unusual qualities of leadership and had been Jefferson's private secretary. He asked that William Clark (1770-1838) a 2nd lieutenant in the United States Artillery and a brother of George Rogers Clark the well known Indian fighter be appointed co-leader. Both men were born near Charlottesville Virginia. Clark served as equal to Lewis in command of the Expedition and the leaders are referred to as Captains Lewis and Clark in historical records. Clark was a frontiersman and soldier of much experience and contributed greatly to the success of the venture. No regular physician was provided but Lewis had sufficient medical knowledge to treat many of the ills of his company and Clark knew the simple medical practices of frontier life.

After collecting the necessary supplies and selecting a personnel of 27 men the captains placed the Expedition into winter quarters at River du Bois, near St. Louis late in 1803. Rigorous training during the winter fitted the men for the anticipated hardships of the journey. The party with 15 or 16 additional men¹ who were to go only part of the way started up the Missouri River in three boats on May 14 1804. Its instructions were to make a geographical exploration of the country they were to traverse and to gather in-

formation about its natural history and the Indian tribes.

Lewis wrote to President Jefferson on May 29 1803 as follows:

"Dr. Rush has favored me with some abstract queries under the several heads of *Physical History Medicine, morals and religion of the Indians* which I have no doubt will be serviceable in directing my inquiries among that people. Drs. Barton and Wistar have each promised to contribute in like manner anything, which may suggest itself to them as being of any importance in furthering the objects of this expedition."²

The physicians to whom Lewis refers were Dr. Benjamin Rush (1745-1813) Dr. Benjamin Smith Barton (1766-1815) and Dr. Caspar Wistar (1760-1818) all of Philadelphia. Dr. Rush was the outstanding American physician of that day and was professor of the institutes and theory and practice of medicine in the University of Pennsylvania. Dr. Barton³ was professor of natural history and botany succeeding to Dr. Rush's chair at the death of the latter in 1813. He had become greatly interested in the Indians as a young man and was an authority on the subject. Dr. Wistar was professor of anatomy in the university and wrote the first American textbook on anatomy.

To aid in obtaining information about the Indians the following list of queries resulted as recorded by Captain Clark under the heading of "Physical History and Medicine":⁴

- "What is their State of Life as to longevity?
- "at what age do both sexes usually marry?
- "How long do the Women usually suckle their Children?
- "What is the diet of their Children after they wean them?
- "Is polygamy admitted among them?

From the University of Oregon Medical School.

⁴Lewis and Clark Expedition, 7: 183.

What is the State of the pulse in both Sexes, Children, grown persons, and in old age, by feeling the Pulse Morning, Noon & Night & c.?

What is their most general diet, manner of cooking, time and manner of eating: and how do they preserve their provisions?

What time do they usually consume in Sleep?

What are their acute diseases?

Is rheumatism, Purpura or bilious fevers known among them? & does the latter ever terminate in a vomiting of Black matter?

What are their chronic diseases—are palsy apoplexy, Epilepsy Madness, the gutta (or Saffled Neck) and the Venereal disease known among them?

What is their mode of treating the Smallpox particularly?

Have they any other disease amongst them, and what are they?

What are their remedies for their different diseases?

Are artificial discharges of blood used among them?

In what manner do they generally induce evacuation?

Do they ever use Voluntary fasting?

What is the nature of their baths, and at what time of day do they generally use them?

at what age do their women begin and cease to menstruate?"

In addition to preparing for his inquiries among the Indians, Lewis made provision against illness in his own party. In 1803 he estimated that the expense of the expedition would be \$2500 of which \$55 was for medicines and packing. He drew up a list of items needed as medical supplies. The items actually purchased represent some modification of the original list and are indicated in the following statement.*

Bill of Gillespie & Strong for Medicine

Israel Whelden Purveyor Bought of Gillespie & Strong the following articles for the use of M. Lewis Esquire on his tour up the Mississippi River, & Supplied by his Order —

6. 4 oz. Salt M	2.22	Portage	30
1 Walnut Chest	4.50		920 67

The total bill was somewhat in excess of the original estimate. While in St. Louis the Expedition was supplied by Dr Antoine Francois Sangram with additional packages of medicines, a home-made thermometer and some experimental lucifer matches. Sangram was a pioneer among the scientists of the Ohio and Mississippi valleys, with hobbies of chemistry and electricity. He no doubt attracted Meriwether Lewis, especially who was near him from December 12 1803, to May 20 1804, the party having started nearly a week before Lewis himself left St. Louis. Very likely Lewis added considerably to his own stock of medical knowledge from contact with the doctor.

At the beginning of their travel up the Missouri River the men were in fine condition. In the early part of the journey there is but little mention of medical matters, but on July 23, Clark wrote in his journal that one man had a tumor on his breast, which he later opened. A week later several of the men had bad boils. Near the present site of Dakota City Nebraska, on August 14, Clark makes mention of a village of Indians which had been wiped out by smallpox 4 years earlier, stating that the huts had been burned and the wives and children had been put to death "with a view of them all going to a better country." Four days later near the present site of Sioux City Iowa, he wrote "Serjeant Floyd is taken very bad all at once with Bilious Cholick we attempt to relieve him without success as yet." The patient died on the 20th "with a great deal of Composure." This was the only death suffered by the party during the entire expedition. On August 22, there is the item that the men had been troubled with stomach disorders, since leaving the Sioux River from using water of the Missouri River on which floated a scum of mineral matter from a bluff upstream. According to Clark this scum contained alum, copperas, cobalt and pyrites. Lewis took a Dose of Salts to work off the effects of tasting some of the rock from which the material came.

The fall of 1804 found the party at the site of Bismarck, North Dakota, where it prepared to winter among the Mandan Indians. Clark's journal contains a notation dated October 22, stating last night at 1 o'clock I was violently and Sod-

*E. S. Mowry Washington Hist. Quart. 231 27 299-312.

*Lewis and Clark Expedition, 80.

*Lewis and Clark Expedition, 224.

denly attacked with the Rhumetism in the neck [probably spasmodic torticollis] which was So violent I could not move. Capt. [Lewis] applied a hot Stone rapped in flannel, which gave me some temporary ease. ¹⁰ Clark suffered from this attack for several days and on the 25th he adds "R. Fields with Rhumetism in his neck, P. Crusat with the Same complaint in his Legs—the party other wise is well as to myself I feel but slight Symptoms of that disorder at this time." ¹¹

A more serious problem, however soon confronted the leaders, namely venereal infection of the men from the Mandan women. This involved diplomacy in dealing with the Indians as well as medical treatment and discipline of the men who were ordered not to touch the wife of any Indian. The orders apparently were disobeyed or unmarried squaws were available, and on January 14 (1805) Clark writes of sending Sergeant Pryor and five men, with some Indians, to hunt several men who had become infected. On the 21st he writes "One man verry bad with the pox." ¹²

On November 29 1804, there is a brief note "Sergeant Pryor in taking down the mast put his Shoulder out of Place, we made four trials before we replaced it." ¹³ Cold weather also brought frost bite to several of the men and on January 26 Clark wrote "one man taken violently Bad with the Plurisie, Bleed & apply those remedies Common to that disorder." ¹⁴

On February 11 1805 Sacajawea, one of the wives of Toussaint Charbonneau an interpreter engaged by the captains at the winter camp was delivered of a fine boy. ¹⁵ Charbonneau had two other wives among the Mandans but only Sacajawea accompanied him with the Expedition when it resumed its journey. This Shoshone girl who was the only woman with the Expedition had been purchased by Charbonneau from Indians who had taken her captive from her tribe as a little girl. She played a rôle in the later history of the Expedition by gaining a friendly reception for the half-starved party when it reached her own country of the Shoshone Indians, in southwestern Montana. The boy born at Mandan was Sacajawea's first child and the labor was tedious and painful. Clark continued

Mr. Jesome informed me that he had frequently administered a small portion of the rattle of the rattle-snake, which he assured me had never failed to produce the desired effect, that of hastening the birth of the child having

the rattle of a snake by me I gave it to him and he administered two rings of it to the woman broken in small pieces with the fingers and added to a small quantity of water. Whether this medicine was truly the cause or not I shall not undertake to determine, but I was informed that she had not taken it more than ten minutes before she brought forth perhaps this remedy may be worthy of future experiments, but I must confess that I want faith as to its efficacy. ¹⁶

The last item of medical interest noted by Clark at the Mandan village bears the date of February 15. He wrote

one Chief of the Mandans returned from Capt. Lewis's Party nearly blind, this Complaint is as I am informed Common at this Season of the year and caused by the reflection of the Sun on the ice & Snow. It is cured by gently sweeting the part affected, by throwing Snow on a hot Stone. ¹⁷

The journey up the Missouri was resumed on April 7 1805 but little of medical interest is recorded. On May 14 while on the Yellowstone River one of the boats which contained the medical supplies was swamped. ¹⁸ Much of the material was damaged and some was destroyed. Between Maria's River and the Great Falls of the Missouri, on June 10 Sacajawea fell ill. Clark wrote "I bled her." ¹⁹ Four days later Clark noted

"the Indian woman complaining all night & excessively bad this morning. her case is somewhat dangerous. two Men with the Toothache, 2 with Tumors & one man with a Tumor & a slight fever." ²⁰

On June 16 Lewis wrote in his journal concerning Sacajawea, who had not yet recovered that two doses of barks and opium had slowed and strengthened her pulse and made it more regular. He had found it almost imperceptible, or very fast and irregular when it could be felt. There also was twitching of the fingers and of the leaders of the arm. In addition to barks and opium, Clark prescribed mineral water for her. The pulse improved the twitching was reduced and a gentle perspiration came on, with much relief from pain. The woman complained chiefly of distress in the lower abdomen, Clark ascribing it to an obstruction of the menses in consequence of taking cold. ²¹ He continued treatment with barks and laudanum.

The party reached Sacajawea's people in the middle of the summer of 1805 its food supplies exhausted, and in serious straits because of this and the scarcity of game. The Shoshone chief proved to be Sacajawea's brother and a touching story of

the reunion is related. The half-starved explorers were supplied with the provisions enough to meet their immediate needs from the Shoshone's own meager store, and the expedition, which had found itself in an almost desperate situation, was enabled to continue its journey.

The party pushed westward through the Rocky Mountains in September. Food was scarce, due to the lack of game, which was limited to a few pheasants and squirrels. Fish and roots formed a large part of the diet. The going became more and more difficult and the men became weak and debilitated, many suffering from dysentery and skin eruptions. Finally they were obliged to kill a goat for food.

On September 21 Clark wrote "I am very sick today and puke which relieves me."²² On the 24th he continued "Capt. Lewis sick all. Complain of a *Laz* & heaviness at the stomach. I gave rushes Pills to several, eight or more of the men also being ill. On the following day he wrote that Lewis was very sick, and most of the party was complaining. He gave them salts and tartar emetic. He added, "Several men so unwell that they were compelled to be on the Side of the road for Some time, others obliged to be put on horses. I gave rushes Pills to the Sick this evening."²³ Several deer were killed on September 30 and the condition of the men immediately improved with better food. However in a few days the party was obliged to return to dried salmon and roots, with renewed gastrointestinal disorders. Not until they reached the Columbia, near the junction of the Snake River on October 16 were they able to obtain fresh meat, in the form of "some nice fat dogs" which they purchased from the Indians. Everyone's health immediately improved. One of the leaders notes that he came to like the meat of "nice fat puppies."

While in western Montana, Lewis wrote that he tried to learn if the Shoshones had venereal disease among them, and to find out their remedies. Through the interpreter and his wife he was informed that sometimes they were affected, but he was unable to learn of any remedy they employed. "They most usually died of its effects." The captain thought that, because of the isolation of this tribe, both gonorrhea and syphilis must be native to America although he recognized that smallpox, from which the Shoshones as well as most of the other tribes had suffered severely was an imported disease. He also made some observations regarding standards of sexual morality stating that "some of their women appear to be held more

sacred than in any nation we have seen. How ever this was but comparative, and control appeared to be entirely in the hands of the husband, who for a suitable reward would barter his wife for a night or longer."

With reference to childbirth among the natives, Lewis comments on the ease of delivery when the father was an Indian. He notes that when one of the Shoshone Indian women who had been helping the party transport its baggage had halted at a little stream, he inquired of the chief as to the reason. The latter informed him that the woman had stopped to deliver her fourth child and would soon overtake the party. Thus she did in about an hour with her newborn babe, apparently as well as ever.

Clark wrote on October 17 1805, of the numerous cases of sore eyes which he encountered among the natives, not only in the region of Kennewick, Washington, where the party then was, but among the Flatheads on the Kootenoke and Lewis Rivers which they had left some time earlier. Many of the Indians were blind in one or both eyes. Many of the natives also had lost their teeth at middle age, and in others the teeth were worn to the gums, especially in the upper jaw. He ascribed the bad teeth, in part, to the habit among the Indians of eating the "rins & scales" of the dried salmon, which constituted a large item of their diet, along with the flesh, and to sand attached to the edible roots which supplemented the salmon.²⁴

On November 15, 1805 the Expedition arrived at the mouth of the Columbia River after travelling 4134 miles, according to Lewis's estimate.²⁵ Alexander MacKenzie had reached the western ocean through Canada in 1793 but Lewis and Clark were the first explorers to reach the Pacific by crossing the continent between the Canadian boundary and Mexico. Valuable observations and collections had been made and Indian tribes never before seen by the white man had been encountered. After crossing to the south side of the river they built winter quarters at Fort Clatsop, south of the present city of Astoria. The party reached the mouth of the Columbia at the worst part of the rainy season and was faced with a good deal of discomfort until quarters could be completed. Dated December 11 we find this entry: "rained all last night moderately. We are all employed putting up huts or Cabins for our winter quarters."²⁶ Several of the men were beginning to suf-

fer from the excessive dampness four of them had violent colds, one had dysentery a third had tumors on his legs, and two had been injured by dislocations and strains

Here again the problem of food obtruded itself. The Indians, who had learned to barter with the Boston ships and other fur traders, demanded high prices for everything they sold. On December 3 an elk was brought in, providing a much needed change of diet. Seven more elk were killed shortly afterward but because of unusually warm weather much of the meat spoiled and the party had to resort to pounded fish again, resulting in the usual dysentery and weakness. On December 30 four more elk were shot but the animals became scarcer as colder weather came on so that dog meat blubber from a stranded whale, roots and berries served as food for a time. The captains remark that the men had acquired a taste for the flesh of dogs and that while living on it they were in better condition and health than at any time since leaving the buffalo country. In the early spring the annual run of the smelt or eulachon into the rivers from the ocean brought a welcome change of diet in great abundance. From this time on the food supply appears to have been adequate both for the short remaining time at Fort Clatsop and on the journey eastward. A salt cairn for the purpose of obtaining salt from sea water had been built by the party at the site of the present town of Seaside Oregon some miles from Fort Clatsop.

There is also complaint about the incessant rain and the innumerable fleas. The Indians and their lodges abounded with these vermin which could not be kept out of the crowded quarters of the party. Other discomforts are mentioned by Clark as follows. Sergeant Pryor unwell from dislocation of the shoulder Gibson with the dysentery Jo Fields with bites on his legs and Werner with a strained knee.

The sexual standards of the women of the Chinook tribe were unusually lax and venereal disease already introduced by sailors of the fur trading ships, is frequently mentioned. While on a short journey on November 18 Clark encountered some Chinook Indians and noted that he saw four women and some children covered with sores, scabs and ulcers, which he regarded as due to venereal disease. The Clatsop Indians also were commented on. The young women, many of whom were handsome, sought the men of the exploring party apparently with the approbation of their friends and relatives. To save the party a supply of knives and other more valuable articles, the captains divided some ribbon among the men of

the party 'to bestow on their favorite lassies.' Several of the men soon became infected with venereal disease. They were treated with mercury some to the point of salivation.

Although Lewis and Clark found venereal disease very prevalent among the Chinooks and Clatsops who inhabited the region about the mouth of the Columbia River, the early explorers and fur traders make no mention of it or of other diseases among the Oregon Indians, save small pox. Robert Gray in 1792, does not mention it, and Captain Bishop of the ship Ruby who spent some time among the Chinooks in 1795 and described the natives in detail, does not refer to syphilis. Yet 10 years later it was widespread and by 1814 had reached epidemic proportions among the fur traders from their contact with native women. Undoubtedly syphilis and its companion gonorrhea, were introduced by the crews of the fur trading ships that came in increasing numbers. Spread of these diseases was facilitated among the Clatsops and Chinooks, especially by the low sexual standards of these tribes on which comment was made by virtually all of the earlier writers.

Regarding the Indians, Lewis stated that once contracted by them venereal disease continued during life, always ending in decrepitude, death or premature old age although as he thought, from the use of certain plants, together with their diet they did not suffer great inconvenience. He regarded this as especially true among the Chippewa Indians, farther east who used a decoction of lobelia and of a species of sumac. These decoctions were drunk in liberal quantities and were regarded by Lewis as effective both in syphilis and gonorrhea.

Under date of February 7 1806 Lewis wrote that the smallpox had carried off a large number of natives near the mouth of the Columbia. The disease had prevailed 4 or 5 years earlier among the Clatsops and destroyed several hundreds of them. He regarded this epidemic as accounting for the deserted villages along the coast toward the Tillamook district.

During the stay of the party at Fort Clatsop the Indians frequently brought their sick to the captains for treatment. Many of the natives benefited from the medicines administered. One young Clatsop chief cured of some ailment, brought his sister to Captain Lewis as a reward. The captain refused her much to the chagrin of the chief as well as of the damsel, who after remaining about the door of Lewis's quarters for some time departed as had the brother earlier.

The party began its homeward journey on March 23 1806. It explored the Willamette River

as far as the present site of Portland, and continued eastward along the south bank of the Columbia. The large number of eye ailments among the Indians again impressed the leaders. Clark wrote on April 8 when the party was between the Sandy River and The Dalles, concerning an Indian woman who was blind in one eye, and of a man nearly blind in both eyes. He stated that blindness appeared to be more common among the natives of the Columbia than among any other people he had ever observed, and that they almost invariably had sore eyes at all ages, with the loss of one eye very common and complete blindness almost invariable in old age. Clark, like others who commented on this affliction among the Columbia River Indians, was inclined to ascribe it to the reflection of the sun on the water to which the Indians were constantly exposed while fishing and to the fine sands carried by the wind. It is now known that trachoma was very prevalent among many Indian tribes. This disease no doubt caused the eye conditions which the explorers commented upon.

The contact with the white men the previous fall had evidently given the Indians along the Columbia a great deal of confidence in the medical ability of the captains. On April 28 between The Dalles and Walla Walla, Clark stated in his journal that several sick persons were brought to the captains for medical aid. One had a knee contracted by rheumatism, another had a broken arm etc. All were treated, much to their gratification. They were given some eye water which Clark thought would be of more help to them than any other article the party could offer them.

They continued their search for answers to the questions concerning medical matters among the Indians. Lewis wrote on April 30 of trading one of their poorest horses for a very good one with a Chopunnish Indian. He commented on the practice of segregation of menstruating women from the remainder of the family. The daughter of this Indian having arrived at the age of puberty was obliged to sleep at a distance from her father's camp and when travelling to follow at some distance behind. At other camps of this Chopunnish tribe he observed a small lodge with one fire which served as a retreat for the women during menstruation. The men were permitted to approach no nearer than fifty to sixty paces from this lodge and if they desired to convey anything to the occupants they would throw it toward the hut as far as they could and retire.

Clark wrote on May 5 of giving a native some volatile liniment to rub on his knee and thigh for pain. The Indian soon recovered and "has never

ceased to extol the virtue of our medicine. The previous fall, near the Kookoonke River an Indian had been encountered who could not walk because of a tumor on his thigh. Clark wrote on the return trip that he gave him a gentle purge, deaized and dressed his sore and left him some castile soap to wash the sore, which soon got well. This man also credited the captain with curing him, the two cures having given the natives an exalted opinion of Clark's skill as a physician. They came to him in considerable numbers for relief from various ills. The captains considered it pardonable to continue this deception," namely that they were skilled healers, for the Indians would not furnish any provisions without compensation in merchandise and the party's stock of goods by now was greatly reduced. Clark added that he and Lewis took care to give the Indians nothing which could possibly injure them, and that many times medical and surgical relief was afforded in simple cases."

Lewis noted that scrofula, ulcers, rheumatism, sore eyes and the loss of use of their limbs were the most common types of ailments among the Indians of the Columbia. Regarding paralysis of the extremities he wrote that he had seen three instances among the Chopunnish. A chief of considerable note had been afflicted with it for 3 years, being incapable of moving a single limb and lying like a corpse in whatever position he was placed. Yet he ate heartily, assimilated his food, and was in a good state of nutrition. His pulse was good and he understood what went on about him. Lewis thought that the natives' diet of roots and other plants was in part responsible for some of their ailments.

While the party was on the upper Kookoonke River (in Idaho) Clark wrote on May 24 that one of his men (Bratton) was very low, eating heartily but being so weak in the small of his back as to be unable to walk, although every remedy had been employed. One of the men stated that he had seen similar cases restored to health by violent sweats, so at the request of the patient this treatment was undertaken. A hot fire was made in a hole four feet deep and three feet in diameter dug for the purpose. After burning long enough to thoroughly heat the ground, the fire was withdrawn a seat was placed in the hole, the patient being placed thereon, with a board under his feet for protection. The hole was covered with blankets, supported by hoops, and a receptacle of water was handed the patient, with instructions to throw the water on the bottom and sides of the hole. After about twenty minutes in the steam-bath thus produced the patient was removed and

placed into cold water for a few minutes. He then was returned to the hole for about an hour removed again and covered with blankets which were removed one by one until the man cooled off. The account concludes. This remedy took place yesterday and Bratton is walking about today and is much better than he has been.

The Indians requested that the same treatment be applied to the paralyzed chief previously mentioned. The latter was so disabled that he could not sit up at the first attempt but by arranging a system of thongs and guy ropes to support him a second attempt was successful. He suffered some shock, and was given twenty drops of laudanum. The following day he could use his hands and arms. After several repetitions of the treatment he became able to use his legs and felt perfectly well. There is little in the description of either of these cases or their treatment to aid in diagnosis. Since the sweat bath treatment was widely used by the Indians themselves in all parts of the continent it could hardly have been new to this tribe in the Rockies, but perhaps the white man's modification of it and the results they had seen on Bratton caused them to have it tried on the chief.

On reaching the Bitter Root Mountains the party divided into two groups for further exploration and to recover supplies and canoes cached at different points on the westward journey. It was reunited on August 12, 1806, near the junction of the Yellowstone and Missouri Rivers, according to plan. Just before the two groups were joined Captain Lewis was accidentally shot in the leg while hunting and for a time was seriously ill.

Captain Clark was obliged to assume responsibility for the rest of the journey which was resumed on August 17, the party proceeding down the Missouri River. Five days after he was injured Lewis recovered sufficiently to be able to walk for the first time.

After crossing the continental divide and leaving the Oregon Country on the eastward journey the medical notes, as well as notes on other matters, are scanty. The effects of contact with the Luetse, Mandan, Chinook and Clatsop women remained with some of the men who were taken to the Great Falls of the Missouri for rest and treatment with mercury. This item and the wound received by Lewis constitute the chief entrees of medical interest. The party visited a few days with the Mandan Indians with whom it had spent the winter of 1804-05 and then continued the journey down the Missouri reaching St. Louis on September 23, 1806.

The epochal journey planned by the far-seeing Jefferson, and so important in establishing the claims of the United States to the Great West was brought to a successful conclusion with the loss by death of only one man. Judging from the simple narrative of the journals, the party faced a number of serious medical problems. Thanks to the hardiness of the men and the healthy life of the trail, supplemented by such stock of medical knowledge as the captains possessed, there is no indication of permanent disability save of course the effects of venereal disease which must have remained with many of the men in spite of the drastic treatment employed.

REVIEWS OF NEW BOOKS

A CLEAR and concise presentation of facts is made in *Fundamentals of Clinical Neurology*¹ by Merritt, Mettler and Putnam which will aid the student and the physician interested in neurology and its applications in the diagnosis of organic disturbances of the central nervous system.

A small and compact section deals with the examination of the nervous system in a rather rapid and concise way. The intention of the authors was to expose a practical technique for examination of the patient from which all special and finer procedures have been omitted. However a small chapter on the examination of a comatose patient seems to be too brief and may leave the examiner rather helpless.

The second portion of the book deals with the anatomic diagnosis of peripheral as well as central nervous system lesions. This is the most important portion and is beautifully presented with a large number of good anatomical as well as schematic illustrations and photographs. In this presentation great emphasis is put on the structure of the various portions of the central nervous system and especially on their arterial blood supply and their venous drainage which is so commonly neglected in other books on clinical neurology and one remains conscious throughout the text of the cerebral and spinal cord blood circulation and its connections with the rest of the blood vascular system. Anatomic structure, blood supply and function are closely associated and the disorders arising from disturbances in this association are briefly but clearly mentioned and discussed. The chapters on spinal cord syndromes, spinal cord transections, diseases of the cerebellum, tumors of the brain, and vascular lesions of the brain are brief and give a rather incomplete picture of the symptomatology and the pathology associated with these lesions. The section on the anatomic diagnosis includes a chapter on peripheral nerve dorsal root ganglion and ventral column cells on the spinal cord, on the infratentorial brain stem on the cerebellum, on the thalamus and corpus striatum, and on the cerebral cortex. The last chapter deals with the cerebral spinal fluid its circulation function, and composition, the methods of examination, indications and contraindications for lumbar puncture, measurement of pressure and testing of dynamics and also gives an excellent presentation of the pathologic changes seen in the spinal fluid and their diagnostic value. It gives a clear and complete summary of changes occurring in the spinal fluid in various types of cerebral and spinal cord lesions including trauma, meningeal infections, abscesses, bacterial infections, tropical diseases, hemorrhages, tumors, intoxications, and generalized diseases originating in other organs and involving the cerebrospinal fluid pathways.

This is a short and excellent book which should be read by all medical students and kept on the desk of most physicians.

GEORGE FRANK.

THE author's purpose, as stated in the preface of *Color Atlas of Hematology*², is to furnish a color atlas of hematology for medical students, laboratory workers, and general practitioners of medicine. This the author has accomplished in a small book of 201 pages which is easily handled. In addition to the excellent color pictures and a brief description of each normal and pathologic cell type there is also a brief discussion of the hematologic features of various blood diseases with the typical blood picture of each disease. There are short chapters on blood parasites, the Rh factor, and bone marrow.

This book is not just an atlas. It also contains chapters on the more important hematologic techniques, on the normal standards of human blood, and on the blood picture of various laboratory animals. A unique aspect is the beginning chapter on definitions of hematologic terms and the last chapter on hematologic findings in various diseases and conditions arranged in alphabetic form.

Although the material in this book is, for the most part, taken from the author's larger work *Diseases of the Blood*, it is a concise and excellent atlas of hematology. It will be useful to technicians and medical students in the laboratory and to clinicians in the diagnosis of blood diseases.

OWEN HENRIK.

IN the volume *Curare its History Nature and Clinical Use*³ the author presents an exhaustive and critical review of the surprisingly extensive literature on curare. As the author states it, "This book attempts to bring together the stories of the early explorers, the accounts of the botanists, whose search for the many and elusive plants used in the fabrication of curare is by no means concluded, the early investigations of the poisons on animals, the chemical examination of curares, which during the last few years has progressed rapidly, and modern physiological and pharmacological research, culminating in the present extensive clinical use of the drug." The book is well written, the references are complete, and there is a full index. Physiologists, pharmacologists, and clinicians are greatly indebted to the industry and effort of the author for this source book of information and nonscientific laymen will find a wealth of interesting and instructive material in it. The book is timely in view of the renaissance of interest in the therapeutic uses of curare. With respect to this the author's comments merit quotation. "With the pioneer work of Griffith and the investigations of Cullen

finding both Ferdinand and Isabella apathetic alike to his eloquence and to his maps, Columbus found solace in the arms of Beatriz Enriquez de Harana, mother of his second son, Fernando. For the next eight years their Catholic Majesties kept poor Columbus dangling. A drop by drop account of the trickle of hopes and coins that fell into his begging-cup would discourage a Job. But the patience of Columbus was sustained by his fixed idea. At last, deciding that he was a displaced person in Spain, he started out to invade France. Every school-child knows the rest of the story—the romantic halt at La Rabida, the recall to Granada, the last rejection, the second recall near the bridge called Pinos, the episode of the Queen's jewels (she didn't really have to pawn them!) and the final agreement.

On August 3, 1492, three little ships sailed out from Palos with eighty-eight jittery mariners, ruff raff drummed up from the taverns of the town. The leaders, however, were experienced sea men, the brothers Pinzon (Martin and Francisco on the Pinta, Vicente on the Nina). On March 15, 1493 two of the little ships came back to Palos, bringing gold, curios, Indians and probably syphilis. On the shores of a strange new world they had left the sea-wrecked Santa Maria and a sorry group of impromptu colonizers, who ruined both themselves and the natives. Columbus thought America was Asia and never discovered his mistake. The Indians thought the white men were gods, but soon discovered their mistake. Las Casas, dying at 95 in Madrid, left to posterity his *Historia de las Indias*, so horrifying a manuscript that Spain kept it unpublished until nearly the end of the nineteenth century. Oviedo who as a boy saw the supplant Columbus at Granada, spent some time on Haiti as a gold supervisor and in his *La General y Natural Historia de las Indias* mixed bloody and revolting tales of debauchery with his descriptions of tobacco and guano.

Physical ills bothered Columbus little up to the time of his first American journey although the strain of living on frustrated hopes must have been considerable. Probably the driving force of his fixed idea kept his body in tune with his ruling passion. However on Voyage I he complains of "sore eyes, a discomfort that evidently pestered the rest of his life. It has been suggested that it may have been trachoma. Voyage

"Gold Rush" of '93, started on September 24, and was full of misery. Two days out Columbus fell victim to a strange malady. It cast him into a dangerous disease between a pestilential fever and lethargy which deprived him of sense and memory. He was in a stupor at times, and

thought himself at the point of death. This may have been typhus or typhoid or even brucellosis, but it could have been due to febrile attacks of secondary syphilis, clinically more severe in those days than now. In a couple of weeks he felt better but had recurrent attacks over a period of some months. Dr. Garcia Fernandez, ship surgeon on the first voyage, reports jail fever among the crew later supplanted by "tropic fever." But Dr. Alvarez Chanca, physician on the second voyage, reports that at times one third of the men were suffering from some unknown disease called "the scourge." It was during the period between these two voyages that syphilis first became rampant in Europe.

Primary proof of the American origin of syphilis is said to be a treatise against the "serpentine disease" (*Tractado Contra el Mal Serpentina*, Sevilla, 1539) by the Spanish surgeon, Ruiz Diaz de Isla. This author saw the first syphilitics who landed in Europe, and treated them by rubbing their sores with mercurial ointment and by administering guano, the Holy Wood that grew in America and was said to be used by the Indians as an antidote to what ailed them. A phrase found in the original manuscript (1537) is omitted from the printed editions. It reads: "As it is of its very nature contagious, they got it easily and presently it was seen in the fleet itself in a pilot of Palos who was called Pinzon and others whom the aforesaid malady kept attacking."

Now Martin Alonso Pinzon, captain of the Pinta, had gone A W O L on the first return voyage and had stopped in Bayona in Galicia before rejoining Columbus at Palos. The hygienist, Tommaso Ragioni of Ravenna, states that the first epidemic of syphilis began in Galicia in March of 1493, and that the disease was then called *Morbus Galecum*. Ragioni wrote a treatise under that title which he published in Venice in 1537. Since Francisco Pinzon was heard of no more after Voyage I, he is too shadowy a figure to consider. And since Vicente Pinzon kept on being a healthy explorer for many years, he probably did not contract the disease. But Martin Pinzon is said to have died shortly after his return from America, and most probably it is Martin to whom Diaz de Isla refers as the "pilot of Palos who was called Pinzon."

Both Las Casas and Oviedo agree that syphilis originated in America, but Diaz de Isla maintains that his serpentine disease is identical with the "lichen of the Greeks and the kiss-spread mentagra" of Pliny. He further states that the therapeutic action of mercury was unknown during the first fifteen years of syphilis, but later admits that

in anesthesia, curare became fully established as an important and useful adjuvant and today the drug appears to be entering upon a period of trial in a wide variety of conditions. This phase is nearly always encountered with therapeutic agents, that is after emerging from a period of neglect they pass through a period of overuse and then the period of overenthusiasm is often followed by a period of reaction and disappointment. Hence it may be some years before the field of true usefulness of curare is finally evaluated. There will be less disappointment if those who plan to try curare for any purpose consult this authoritative volume.

CARL A. DRAGSTEDT

THE account of the isolation and application of folic acid to the macrocytic anemias presented by Dr. Spies in *Experiences with Folic Acid*¹ is a brief and readable corollary to the volume published last year on the biological aspects of the blood dyscrasias. As the author points out in his introduction this important medical discovery was the result of work carried on in many different laboratories. Intimately associated as he has been from the biochemical as well as the clinical viewpoint Dr. Spies is admirably qualified to integrate and summarize the steps which have been accomplished toward an understanding of the pathogenesis and treatment of pernicious anemia and the related anemias.

The introduction is a simple but complete account of the breaking down of potent liver extract and the assay of its chemical constituents. It is followed by a chapter on selection of subjects and methods of study which provides not only a fascinating account of experience with folic acid but a notable example of large scale clinical research excellently directed.

The studies were carried on in centers in Cincinnati, Birmingham, Havana, and San Juan, Puerto Rico. The criteria for the selection of patients were carefully defined and were adopted in all hospitals involved in the study and the rules for management were rigidly adhered to. The response to folic acid is discussed on the basis of 78 cases of Addisonian pernicious anemia, 76 of tropical sprue, 2 of nontropical sprue, 46 of nutritional macrocytic anemia, 3 of macrocytic anemia of pregnancy, 8 of nutritional leucopenia, and 5 of cirrhosis of the liver. Hemopoietic response was satisfactory in all cases except several of the cirrhosis group.

A pure synthetic substance has thus been found which causes regression of the symptom-complex associated with the macrocytic anemias and remission of the blood picture. There is slight evidence that it will prevent neural disturbances in pernicious anemia.

EDITH B. FARMSWORTH

THE four hundred and thirty page book *Diagnostic neuro-surgical* by Guillaume and Sigwald² is to our knowledge the first book on neurosurgical diagnosis published in France and written by two French

neurosurgeons. Throughout its 430 pages its authors stress the necessity of making an early diagnosis in order to perform an early operation before irreversible damage and changes have taken place in the cerebrum. Their main objective is to familiarize the practitioner with the diagnosis of neurological conditions which can be helped by surgery. They make him conscious that not only intracranial tumors need early operation, but that other neurologic diseases may benefit greatly from surgical intervention diseases such as types of epileptiform seizures, hydrocephalus, acute cerebral hemorrhage and certain neuralgias involving cranial and other nerves.

The first part of this book deals with the surgical anatomy, physiology and pathology of the brain and a short anatomical and histological study is made of the various intracranial tumors. The reaction of the brain to neoplasms and increased intracranial pressure is also presented. The second part deals with the symptomatology of the neurosurgical lesions of the brain and includes chapters on the generalized symptoms and the local symptoms produced by tumors and their effect on the various cerebral functions. Examination of the patient and the more important diagnostic procedures are briefly mentioned.

In the third part of the book, which is the most important, the authors study the clinical pictures produced by space occupying lesions in relation to their location and the nature of the lesion and discuss the diagnosis and the possible abnormalities found in radiographies, encephalographies or ventriculographies of that region. A short chapter is devoted to the anatomical and clinical study of craniocerebral injuries and their complications and sequelae. Three chapters deal with the spinal cord and the peripheral nerve root. The anatomy and physiology of the spinal cord is briefly reviewed, mostly from a surgical point of view and the syndrome produced by various types of lesions in relation to their location are explained in a short and concise presentation. The symptomatology, etiology, the clinical form and the various diagnostic problems of spinal cord compression are discussed with more detail. The last two chapters are dedicated to the study of nerve root compression and spinal cord injuries.

Operative techniques and methods are not discussed and are hardly mentioned but the danger of spinal puncture in cerebral tumors with increased intracranial pressure and in acute craniocerebral injuries is emphasized. The authors follow very strict indications for the performance of diagnostic procedures such as spinal punctures, air studies or myelographies. Most of the illustrations are schematic drawings; the pictures are few but they are well chosen and expressive.

GEORGE PERRET

THE aim of the book to set out concisely the principles of operative surgery with adequate detail has been admirably done in *Eye Surgery*³ by H. B.

¹EXPERIENCES WITH FOLIC ACID. By Tom D. Spies, M.D. Chicago: The Year Book Publishers, 1947.

²DIAGNOSTIC NEURO-SURGICAL. By Jean Guillaume and Jean Sigwald. Paris: Presses Universitaires de France, 1947.

³EYE SURGERY. By H. B. Ballard, M.B.E., M.D. (Cambridge), F.R.C.S. (Eng.). Baltimore: A Williams Wood Book. The Williams & Wilkins Co., 1946. Printed in Great Britain by John Wright & Sons Ltd., Bristol.

Stallard. The book was written at sea, in military transports, and in camps amidst distractions and without access to the ophthalmic literature, which in places gives it an urgency and personal appeal that makes it less dogmatic than the usual textbook on surgery.

The repetition as to anesthesia and the instruments make the book appear as though each subject was prepared for a new group of associates.

One misses the frequent references to the names in the literature of the history and development of each operation but each subject is taken up in the practical application of details under the harassing circumstances of war.

The introductory chapter discusses the operating room layout, staff discipline care and maintenance medication, anesthesia, sterilization, general post operative treatment, and dressings.

Much space is given for the general principles of plastic surgery and the operative technique for reconstruction of the lids after war injuries, and there is discussion of civil and military accidents.

The surgical anatomy is given in detail of each subject presented and the possible complications emphasized in regard to the major and minor surgical procedures.

The use of diathermy and katholysis in the treatment of hemangiomas of the retinae as well as of retinal separation is given and the application of radon seeds for the treatment of glioma retinae and for malignant melanoma of the choroid. Illustrations are concise as are the details for the excision of a tumor of the choroid.

The author's results in statistical form with the operative procedures are included in the care of retinal separation hemangiomas of the retinae and of the use of radon seeds in malignancy.

It is an excellent book on surgery which is small enough that it can be easily carried about for quick reference and also gives the details for the eye surgeon who does not operate frequently.

BRUCE CURRIE.

It is now twenty two years since Professor Boyd first wrote his *Surgical Pathology* and during that time he has published six editions. The sixth edition, which is now at hand, affords ample evidence for the long popularity of the book. Designed not for the professional pathologist, but rather for the practicing surgeon and the student who is preparing himself to take the examinations of the American Board of Surgery this book is readable, comprehensive, and modern. Professor Boyd is well known for his lucid style, his wit and his gifts as a teacher. Such qualities, which are all too rare in medical books, add greatly to the value of this one and to read it is a profitable experience.

New material includes a critical review of the etiology of cancer with discussion of Bittner's milk

factor in relation to carcinoma of the breast, of avitaminosis in cancer of the mouth, and of Papain-colou's vaginal smear method in diagnosing cancer of the cervix uteri. Because of the recent interest in the surgical treatment of certain congenital diseases of the heart an entirely new section has been added dealing with the pathological physiology of such lesions. Other new material includes a discussion of fibrous dysplasia of bone, inflammatory nodules of muscle in chronic arthritis, and fibrositis of the back.

WILLIAM B. WARDMAN

AFTER a period of 5 years, a second edition of Duncan's extremely valuable volume on *Diseases of Metabolism* has appeared. The chapters on special subjects are written by our leading authorities. They have been brought up to date, each chapter closing with a recent bibliography. The chapter on carbohydrate metabolism is by Professor C. N. H. Long and contains a clear and very complete exposition of the biochemistry of carbohydrate metabolism. That on protein metabolism is by Professor Abraham White with references to the newer work in electrophoretic studies of the plasma proteins as well as isotope studies of the intermediary metabolism of proteins. The chapter which deals with lipid metabolism was also written by Professor White and is followed by 206 references many of them of the literature of 1945.

The review of the mineral metabolism is by Professor Cantarow. It covers pathological clinical conditions as well as physiological mechanisms. The chapter on water balance is by Professor Peters of Yale University and is very complete. There is an interesting article on the subject of the metabolic aspects of blood disorders by Dr. Tocantins which gives a comprehensive review of the metabolic aspects in hematology. The vitamins and avitaminosis are extensively reviewed and illustrated by Dr. Spies and Dr. Butt.

There is a chapter on undernutrition by Professor L. H. Newburgh of Ann Arbor. Obesity is covered very thoroughly with explicit directions and many menus by Dr. Frank Evans.

Disturbances of intermediary metabolism, gout, diabetes, hyperinsulinism, are each covered by an outstanding authority. The present edition includes two new chapters. The diseases of the kidneys are described by Dr. Max Miller and Dr. Joseph M. Hayman, Jr. and disorders of the thyroid gland is a subject which is dealt with very completely and with comprehensive descriptions of iodine metabolism by Professor Alexander Winkler of Yale University.

This accumulation of modern and authoritative material on diseases of metabolism renders this volume one of great value to the student, intern, and surgeon who wish the last word on this subject.

PAUL STARR.

THE concise, well edited methodical *Year Book of Neurology, Psychiatry and Neurosurgery*¹ brings in 700 pages a good summary of the important publications on neurology, psychiatry and neurosurgery published during the years of 1945 and 1946. Numerous important articles published in foreign countries have also been abstracted and broaden our contact with the great schools of Europe and South America.

The section on neurology emphasizes certain new acquisitions of knowledge of neuroanatomy and physiology. Numerous articles on the effect of new drugs on convulsive seizures such as tridione have been abstracted. A special place is given to the therapeutic effect of streptomycin, penicillin and the sulfonamides on the various types of meningitis and cerebral infection. Also the use of penicillin in neurosyphilis is widely discussed. The chapters on disorders of the cerebrovascular system and cerebral infection and intoxication show the great importance placed on the studies of these disorders.

The section on psychiatry includes a chapter on child psychiatry, schizophrenic reactions, toxic psychosis, psychosomatic disorders, military psychiatry and therapy. Interesting articles are abstracted on the psychiatric complications of tropical diseases, malaria, poliomyelitis, chronic inflammation of the central nervous system, head injuries, tuberculosis, and various other intoxications. Other articles deal with the psychiatric factors in duodenal ulcers and

other gastrointestinal disorders and their treatment. The psychiatric aspect of various skin affections is also well presented. The last chapter deals with numerous articles on shock therapy, its physiologic basis, its effects and complications, the use of various drugs, and some reports on the result of prefrontal lobotomies in psychiatric disorders.

For the first time a separate section in this year book is given to neurosurgery. As a direct result of research stimulated by the war and of war casualties an increasing number of articles published in the past year deal with nerve injuries and craniocerebral injuries and their treatment. The use of sulfonamides and penicillin has greatly reduced the instances of infection of intracranial wounds and has altered the methods of treating them and also of treating brain abscesses. Various types of peripheral nerve lesions and their treatment are discussed. Numerous articles also are related to the complications of peripheral nerve lesions, such as causalgia, phantom limb pain and related painful syndromes, and the various ways of treating them are presented. Other chapters deal with sympathetic surgery, the surgery and the diagnosis of herniated intervertebral discs and related myelopathies and spinal injuries. A few articles on intracranial vascular lesions and intracranial tumors are also abstracted. A new hemostatic agent, gelatin sponge, other new therapeutic methods, and operative procedures have found their important place in this book which is invaluable for the busy and interested physician who does not always have the time to read the various and numerous special used publications published all over the world.

GEORGE PERRET.

¹1946 YEAR BOOK OF NEUROLOGY, PSYCHIATRY AND NEUROSURGERY. Edited by HANS H. REINE, M.D., and MABEL G. MASTEN, M.D. for the section on Neurology; by NOLAN D. C. LEWIS, M.D. for the section on Psychiatry; and by PIERCE BAILEY, M.D. for the section on Neurosurgery. Chicago: The Year Book Publishers, 1947.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

TRICHOMONAS VAGINALIS AND TRICHOMONIASIS. By Ray E. Trummel, M.D. Springfield, Ill.: Charles C. Thomas, 1947.

CORRESPONDENCE

PLASMA CLOT GRAFT OF PERITONEUM FOR PERFORATIONS OF STOMACH

To the Editor: May I comment briefly on the article entitled Plasma Clot Graft of Peritoneum for Perforations of Stomach by Dr Joseph Bloom which appeared in the August, 1947 number of *SURGICAL GYNECOLOGY AND OBSTETRICS*? Dr Bloom used 9 dogs in his experiments, 4 of which survived. He explained the failures on the basis of mechanical defects in the technique of applying the grafts rather than as being due to digestion by the gastric juice and this in spite of the fact that digestion was described in the protocols of some of his experiments.

It is my feeling that no graft of tissue can be used to close a defect in the stomach wall successfully unless something is done to protect the graft from the action of the gastric juice. Price and Lee have recently shown that virtually all living tissue when used as implants in the stomach wall are subject to digestion by the gastric juice and that the rate of digestion is greatly speeded up in the hyperacid stomach.

Neuhof¹ in 1917 attempted to repair defects in the stomach by the use of living fascia. In all instances the implanted fascia was digested by the gastric juice and perforation occurred. He found however that if gastroenterostomy was also performed perforation was prevented and satisfactory healing ensued.

In 1920, I² published the results of experimental work in which I used alcohol preserved ox fascia lata to repair defects in the stomach wall. In my early experiments perforations did not occur and I wondered if alcohol preserved fascia was more resistant to gastric juices than living fascia. This however did not appear logical as there was no reason for believing that the collagen fibers of the connective tissues were altered either chemically or physically by preservation in alcohol. I did not have to wonder about this long because in the next cases in the series the fascia in each instance became perforated due to digestion. I then did 5 cases in which I was able to prevent digestion of the implant by giving the dogs 3 ounces of bismuth subnitrate by stomach tube on the operating table as soon as the defect in the stomach was closed and then giving them 1 ounce daily in milk for the following 2 weeks. The bismuth probably protected the implant from gastric juice by forming a mechanical coating over it.

In view of the experiments of Neuhof, Price and Lee and myself I do not see how Dr Bloom can ex-

pect his peritoneal grafts to be successful as a routine procedure. Price and Lee have shown that while fibrous connective tissue is one of the most resistant of living tissues to the action of gastric juice. In spite of this, Neuhof's fascial implants were all digested unless he diminished the action of the gastric juice by performing a gastroenterostomy. Some of my implants of preserved ox fascia lata were digested and some were not. Apparently they could be protected as a routine by giving large doses of bismuth subnitrate. Certainly the experimental work already done is discouraging for the use of any tissue as an implant to repair a defect in the stomach wall. If the implant does remain intact however the ultimate result is excellent. In my successful experiments, the implant became covered on the outside with gluing peritoneum with very few omental adhesions attached. The inside of the implant became covered with gastric mucosa which was perfectly normal in appearance.

I do not believe that oxycellulose gauze used as a plug on the inside of the graft by Bloom in some of his experiments, could be counted upon as a routine to protect the graft from the action of the gastric juice. Oxycellulose gauze implanted among living tissues soon becomes a mushy mass (unpublished experiments of my own) incapable of protecting a graft from the action of the gastric juice until the gastric mucosa could have time to grow across it.

Baltimore, Maryland.

AMOS R. KORTZ.

THE PLASTIC SURGICAL CLOSURE OF DECUBITUS ULCERS IN PATIENTS WITH PARAPLEGIA

To the Editor: In the September issue of *SURGICAL GYNECOLOGY AND OBSTETRICS*, pp. 331-332, an article entitled The Plastic Surgical Closure of Decubitus Ulcers in Patients with Paraplegia appeared under my name and that of several of my assistants at the Veterans Hospital, Bronx, New York. Apparently I did not conform to the procedure of the Veterans Administration in that I failed to obtain permission of the Chief Medical Director of the Veterans Administration to publish this article.

Information has come to me that the Chief Medical Director has given his permission and that there is a standard footnote which should be published under such article. This footnote reads as follows:

Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

the Arabs seem to have known about it. The three types of his serpentine disease correspond roughly to the three stages of syphilis.

It seems odd that so universal a disease as syphilis could have once been confined to the island of Haiti, and that the handful of sailors who returned with Columbus from the first voyage could have contaminated the whole of Europe within eighteen months. But it is just as odd that no pre-Columbian syphilitic skull has appeared in Europe, although many have been dug up in America. Microbial evolution may account for the change in a hitherto innocuous germ, since definite variations in virulence are known to occur in bacterial transition to a strange host. Certain it is that a syphilitic tidal wave engulfed Europe in the closing years of the fifteenth century. Isolated disease descriptions by medieval writers suggest various syphilitic stages, but there seems to have been no widespread contagion prior to the return of Columbus. However it should be noted that the close of the century marked the break-down of the so-called leprosy of the Middle Ages into a dermatologic potpourri, some of which may have been venereal. And to say that Charles VIII and his army spread the new disease as they returned from the siege of Naples in 1496 is an anachronism for historians now agree that there was no such siege.

That the illness of Columbus on Voyage II was due to secondary syphilis is, of course, possible. But it should be noted that his trials and tribulations while visiting the newly discovered islands of the West Indies were enough to aggravate any infection. He had almost no sleep for thirty three days, and was utterly exhausted by the terrible wear and tear of mind and body. Leaving his colonists racked by sickness and hunger he returned to Cadiz in June of 1496.

Two years later he set out on Voyage III and this time he is said to have been incapacitated by a severe attack of gout, followed by a violent fever. This is the first time that he suggests any pain in his joints. That he really had gout is doubtful, for gout seldom affects so abstemious a man as Columbus. Furthermore his illness was accompanied by a high fever and occurred for the first time during the summer months. Nor was it confined to a few of the smaller joints. Rheumatic fever has been suggested, but ordinarily rheumatism does not resolve into chronic rheumatism of the kind with which Columbus continued to be afflicted. His joint pains eventually subsided into what seems to have been chronic polyarticular arthritis. The pain and rigidity became gradually progressive and never left him. In

general the account of his malady sounds like rheumatoid arthritis, starting with an acute attack accompanied by high fever. The conditions under which he lived could very easily have furnished the predisposing and exciting causes.

In *Authentic Letters of Columbus* translated by J. I. Rodriguez, the Admiral writes to son Diego "The ailment which afflicts me is so bad and the cold weather aggravates it so much, my illness prevents me writing except at night. In the day time my hands have no strength. In rheumatoid arthritis the hands are often the first to be affected the fingers eventually becoming gnarled and rigid."

It was during this same voyage that his companions noted the peculiar condition of Columbus's mind. On Christmas Day 1499 he seemed strangely introverted and spent long hours in self absorption. Of this occurrence Columbus himself relates that he heard a voice from heaven saying "Take courage. Be not afraid, nor fear. I will provide for all."

His return journey was made in chains. Much abuse has been heaped upon Bobadilla, newly appointed governor of the new islands for his cruel and dishonorable treatment of Columbus but with self-conscious martyrdom for he directed that his chains be buried with him. To be shipped back home like a common felon could have aroused sufficient emotional trauma to produce at least a few psychopathic symptoms. The reason for Bobadilla's actions may be laid in his own inferiority complex, a mass of fear ignorance and jealousy conflicting with Columbus's simple inhumanly self righteous, and rather domineering manner. Although Columbus was a natural commander he was no organizer and probably had an irritating tendency to make a mess of administrative affairs.

But it is also possible that Bobadilla suspected that Columbus was insane and simply took the usual measures of dealing with men possessed with a devil. Such men may have been merely possessed of a sputhete. On the other hand geniuses frequently feel themselves to be inspired and Columbus's conception of himself as the Christ Bearer to the New World may have had a purely psychological basis born of implicit faith in his own great destiny and encouraged by adulation and honors heaped upon him after Voyage I.

On the way home he wrote a long confused letter to Doña Juana de la Torre friend to Isabella a letter that to some psychiatrists gives evidence of a psychotic mind. Upon arrival his chains were removed and both he and Isabella

COLLECTIVE REVIEW

THE CAUSES AND TREATMENT OF SCIATIC PAIN

CHARLES GRAY B.Sc., M.B., Ch B F.R.C.S London England

"Observational inquiry in clinical medicine may give results that are questionable on the one hand because too much value has been given to conclusions essentially based on intuition and on the other hand because the possibilities of exact observation and record have been exaggerated. We are all familiar with instances of large and imposing masses of records vitiated at their very base by the preconceptions of their compilers, or by the impossibility of precise records, and with instances of the hieratic pronouncement that rises superior to the need for proof."

Wilfred Trotter

"The development of a special sense is often followed by the atrophy of common sense."

Arbuthnot Lane.

"It is necessary not only to find the cause of the patient's disability and to remove it, but also to convince him that he has been relieved and that he is able to return to his work."

J Grafton Love and Maurice Walsh
writing on "Protruded Intervertebral Discs."

THE prolapsed intervertebral disc is now regarded by many authorities as the commonest if not the only cause of sciatic pain. This is a view which has gained wide support during the War. It is probable that during the war years there has been an absolute increase in the frequency of prolapsed discs, because large numbers of young men have been removed from their normal environment and subjected to abnormal strains for which many of them were unfitted. At the same time these cases have been segregated in "centers" where large masses of records have been compiled. These are necessarily the records of highly selected series, and they tend naturally to exaggerate the relative importance of the prolapsed disc.

It is, of course, true that when sciatica is accompanied by abnormal neurological signs the clinical aspect is that of a lesion at the root level, of which a prolapsed disc is a very likely cause. But even in such cases, actual observation shows that the prolapsed disc does not account for all cases.

Honorary Orthopedic Surgeon, Royal Free Hospital, London.
Consultant in Orthopedic Surgery British Post Graduate Medical School

every surgeon familiar with this problem knows that in some of them the discs are found to be normal at operation.

The other group (it is numerically important) in which there are no abnormal neurological signs, contains cases in which the pain is referred. For these there are several possibilities in diagnosis. The prolapsed disc is not the only factor.

It is proposed in this article to review the nature and causes of sciatic pain and to recount the results obtained with various methods of treatment in a series of 298 cases.

TABLE I — 298 CASES OF SCIATIC PAIN

Military	104	Not
Civilian	145	selected

THE NATURE OF SCIATIC PAIN

A. There is an important element of referred pain in most cases of sciatica.

Thus, we find that sciatic pain can nearly always be abolished by a local subcutaneous injection of novocain over the painful area.

Fig. To illustrate the mechanism of referred pain, as demonstrated in Kellgren's and Elliott's experiments. PPD = posterior primary division. APD = anterior primary division.

Further in cases of sciatica we constantly find a tender area over the sciatic notch. Local subcutaneous injection of novocain at this tender area abolishes the tenderness, and, more surprising, it causes Lasègue's sign to disappear or to become much less marked.

When Kellgren's experiment stimulating the spinal ligaments with 6 per cent saline solution (Fig. 1) is repeated we find that the injection always causes local backache at the site of injection. It sometimes causes, in addition a referred pain in the leg. This pain is not referred as Kellgren believed on a segmental basis. It is inconstant in distribution, in the nature of a dull aching discomfort, and poorly localized. The patient has difficulty in saying exactly where it is. The pain is, in fact, very similar to that in many cases of sciatica. It is immediately relieved by a subcutaneous injection of novocain over the painful area. And of course an injection of novocain into the spinal area which was stimulated will immediately abolish both the local backache and the referred pain.

It will be remembered that Elliott investigated sciatica of various types, including several cases of proved prolapsed disc. Using the electromyograph he showed that in sciatica of all types the pain is associated with muscle spasm in the painful area. He then repeated Kellgren's experiment producing referred sciatic pain artificially by chemical stimulation of the spinal ligaments with 6 per cent saline solution. This pain also was

shown by the electromyograph to be associated with muscle spasm.

Elliott considers that muscle spasm may be responsible in cases of sciatica for a considerable part of the patient's total discomfort. The spasm may be produced either by direct irritation of a nerve root as in the cases he investigated in which a prolapsed disc was subsequently found at operation, or by a stimulus which arises outside the nerve roots, through a reflex path involving the anterior horn cells. In the latter case, referred sciatic pain is produced by stimulation of those posterior primary divisions whose corresponding anterior primary divisions form the sciatic system (Fig. 1). The experimental demonstration of this by Kellgren's method of chemical stimulation has already been mentioned. The clinical application depends upon the anatomical distribution of the nerves concerned.

The anterior primary divisions of the fourth and fifth lumbar nerves and the first, second, and third sacral nerves take part in the formation of the sciatic nerve. The spinal musculature, the intervertebral joints, the posterior common ligament of the spine, the ligamentum flavum, and the interspinous and supraspinous ligaments are innervated by the posterior primary divisions of the same nerves and by recurrent twigs (nervus rami vertebralis, Luschka) formed of branches from the spinal nerves and from the sympathetic chain, which turn back into the spinal canal through the intervertebral foramina. Stimuli originating in these spinal structures may cause pain which is referred to areas supplied by the anterior primary divisions of the spinal nerves concerned.

Cases of referred pain are numerically important. In our series of 249 consecutive cases, there were 129 (52%) of the referred type without neurological signs.

B So far as direct sciatic pain is concerned, it is obvious clinically in many cases, that the nerve is affected at a root level. In this connection the anatomical relations of the roots are important.

The nerve roots leave the canal via the intervertebral foramina. The foramina are pear shaped, with the narrow end downward (Fig. 2) and the roots lie in the narrow inferior parts of the foramina. (Fig. 3) In the lumbar region the foramina become progressively smaller as the spine is descended. The nerve roots, however become larger and so the lower lumbar nerve roots, which are the thickest, lie in the smallest lumbar foramina (Danforth and Wilson) and what is more, in the narrow inferior parts of these apertures, to which they are anchored by thin bands of fibrous tissue, which sometimes are shown by dissection (Fig. 7.)

Fig. 2

Fig. 2. Model to show intervertebral foramina. Note particularly the lateral extension of the ligamentum flavum and its attachment to the capsule of the lateral joint. The foramina are pear shaped.

Fig. 3

Fig. 3. Nerve root in narrow inferior part of foramen closely related to disc, lateral joint, and ligamentum flavum.

Fig. 4

Fig. 4. Model showing attachment of ligamentum flavum to lamina and articular process.

As they run obliquely downward and outward through the foramina, the nerve roots are related

1 Anteriorly to the intervertebral disc and to the margins of the vertebral bodies above and below. Note that the anterior wall of that narrow inferior part of the foramen in which the nerve root lies is formed principally by the disc. The relation between disc and root is intimate.

2 Posteriorly to the ligamentum flavum to the capsule of the lateral joint and to the antero-lateral surface of the lower articular facet.

The ligamentum flavum is normally from 2 to 3 mm. thick. It is attached below to the upper margin of the lamina of the lower vertebra and extends laterally to a variable extent as a continuous sheet attached to the anterior and upper borders of the upper articular facet of this vertebra, and to the capsule of the intervertebral joint (Fig. 4). Above, the ligamentum flavum is attached to the anterior surface of the lamina of the upper vertebra and to the anterior surface of the root of the lower articular process of this vertebra across which it extends laterally to a variable extent toward the root of the transverse process. There is a free lateral border which forms the posterior boundary of the outer mouth of the intervertebral foramen. This lateral border is closely related to the issuing nerve root (Fig. 5).

Each foramen transmits a spinal nerve, sympathetic filaments, blood vessels, and lymphatics.

The space is normally adequate to contain these structures and their surrounding fat, but there is little room to spare and minor pathological changes in the walls of the foramen may suffice to cause pain.

Emerging from the foramina the nerves divide into the anterior and posterior primary divisions and the fourth anterior primary division turns downward in front of the transverse process of the

Fig. 5. Dissection of lumbar spine viewed from the side. The fourth, fifth, and sixth transverse processes have been removed. The third, fourth, and fifth nerves are seen emerging from the foramina. At each foramen the lateral edge of the ligamentum flavum is clearly seen, in contact with the issuing root forming the posterior boundary of the intervertebral foramen.

Fig. 8.

Fig. 9.

Fig. 10.

Fig. 8. Oblique view of lateral joints (Normal).
 Fig. 9. Oblique view to show arthritic change in lumbosacral lateral joint.

Fig. 10. Roentgenogram showing arthritis of lateral joint in ankylosing spondylitis. (Film lent by Dr. Campbell Golding).

ical arthritis, frequently demonstrable in good roentgenograms. This arthritis might influence the adjacent nerve root either by swelling of the joint itself or by an associated periarticular edema and engorgement. And clearly an arthritic lateral joint (innervated by the posterior primary division of a spinal nerve) might be a source of referred pain. Putti interpreted the stiffness of the spine, so often associated with sciatica, as a clinical sign of spinal arthritis. Lateral deviations of the spine (sciatic scoliosis), he also regarded as a product of spinal arthritis.

Bankart agrees with these views of Putti, but there are not many other supporters. In fact the idea has been dismissed in a summary fashion by some writers (Hurst). The available evidence concerning the theory is given herewith.

We have already pointed out how close is the relation between the lateral joints and the nerve roots. As the root enters the intervertebral canal it lies actually in contact with the capsule of the corresponding lateral joint (Fig. 6).

In some specimens which we dissected, osteoarthritic changes had occurred in the lateral joints, and were associated with remarkable changes around the nerve roots. Adhesions of varying density had formed around the nerve roots in the intervertebral foramina (Fig. 7). In one specimen there was also a dense fibrosis around the nerve roots, outside the intervertebral foramina where they lie on the lateral aspect of the

vertebral bodies, at the roots of the transverse processes. Here they were surrounded by dense fibrous tissue, and could be separated from the bone only by sharp dissection. The fibrous network was intimately connected with the adjacent muscles. Putti and Logroscino made similar observations. In many specimens they found arthritic changes in the joints with ulceration and fibrillation of the articular cartilage, hypertrophic synovial villi, loose bodies, capsular edema, and adhesions between the joint capsule and the meningeal covering of the adjacent nerve roots. In some cases arthritic changes which could not be detected radiologically were found on dissection. From these investigations Putti concluded that arthritic changes are present in the lateral intervertebral joints of most people more than 40 years of age.

Unfortunately it is more difficult to demonstrate arthritic changes in the lateral joints of the living subject. The clinical signs, stiffness of the spine and pain on forced movements, are obvious but these signs may also be produced by other lesions, for instance by degeneration of the intervertebral discs. Roentgenography the obvious "court of appeal," is useless unless the films are absolutely "first class," a standard not always attained in routine work. Thus, we examined the roentgenograms of the 298 cases which are considered in this article, but the results were not worth reporting so far as the lateral joints were

Fig. 11. A case of bilateral sacralization of the fifth lumbar vertebra. In the lateral view marked congenital narrowing of the fifth lumbar disc is seen. There is, in addition, acquired narrowing of the fourth disc with slight posterior displacement of the fourth lumbar body and osteophyte formation on the posterior lower edge of this.

concerned, because in many of the films these joints were not clearly shown.

What then is the position of spinal arthritis considered as a cause of sciatica?

1 Arthritis of the lateral joints does occur and is probably common.

2 For technical reasons it is difficult to demonstrate arthritis of the lateral joints.

3 On anatomical and physiological grounds it appears that arthritis of these joints may cause sciatica, either as a referred pain, or because of associated periradicular changes. It is an explanation which may reasonably be considered when the clinical picture is that of a lesion at root level but the discs are found to be normal at operation.

In our consecutive series of 249 cases, spinal arthritis was considered to be the responsible factor in 41 cases (17%).

In connection with lateral joint arthritis the association of sciatica with ankylosing spondylitis is interesting. This disease sometimes presents itself as sciatica. Golding recorded 98 cases, of which 14 (11%) had at first been diagnosed as sciatica. In our series of 298 cases there were 4 in which the sciatic pain was a symptom of

ankylosing spondylitis. In all 4 cases the pain was of the referred type—there were no abnormal neurological signs. It seems likely that in such cases the sciatic pain is caused by the lateral joint arthritis which occurs in ankylosing spondylitis (Fig. 10).

Sacralization of the fifth lumbar vertebra occurs frequently as a congenital anomaly and does of course, materially alter the circumstances in which the fifth lumbar root leaves the spine, but since the nerves and the vertebral column develop *pari passu* it seems improbable that the enlarged transverse process, as such would affect the function of the fifth root. Secondary pathological changes may possibly do so. Thus, the joint between an enlarged fifth transverse process and the lateral mass of the sacrum may become arthritic and so affect the contiguous nerve root. If the sacralization is unilateral it seems likely that abnormal strain may be thrown upon the lower lateral joints on the opposite side, predisposing them toward arthritic change. The most important result of sacralization, however is the altered status of the *fourth* lumbar disc. Sacralization fixes the fifth lumbar segment. It follows that the maximum strain which normally falls upon this

segment as the lowest point of the mobile spinal column must now be taken by the fourth lumbar disc. Hence, there is in these cases a tendency toward degeneration of the fourth disc. This has been noted by Capener. The patient whose roentgenograms are shown in Figure 11 is a case in point. There is bilateral sacralization of the fifth lumbar vertebra, with congenital narrowing of the lumbosacral disc. There is also acquired narrowing of the fourth lumbar disc, with osteophyte formation at the lower posterior angle of the fourth lumbar vertebra.

Acquired narrowing of an intervertebral disc may be distinguished from congenital narrowing by the associated sclerosis of the adjacent bone margins and by osteophyte formation at their edges. The pathology of disc degeneration with subsequent narrowing causing arthritic changes in the spine has been studied by Keyes and Compere. A narrow disc affects the size of the corresponding intervertebral foramina (Hadley). Subluxation of the lateral joints occurs with upward displacement of the lower articular facets and slight backward displacement of the upper vertebral body in relation to the lower (Fig 11). Both these factors decrease the size of the foramen, and the combined effect may be significant, especially in the case of the lumbosacral junction, where the smallest foramen of the lumbar series transmits the largest lumbar root.

Meyerding (62-63) quotes a series of 745 patients with spondylolisthesis of whom 10.7 per cent had coincident sciatica. Nearly all of these patients had either grade I or grade II spondylolisthesis. There is, of course, a possibility of pressure by the posterior edge of the lower vertebra and, in addition, spondylolisthesis increases the risk of protrusion of a disc.

Our series includes one case of spondylolisthesis, but laminectomy revealed no prolapse.

Lesions of the sacroiliac joints are not often the cause of sciatica. Sciatica of a referred type, without neurological signs, is occasionally associated with sacroiliac strain, and both are relieved by manipulation. Porter mentions 3 cases of sacroiliac tuberculosis in which sciatic pain was present. I have never seen osteoarthritis of the hip joint as a cause of sciatica although it is often described as such.

Sciatic neuritis. Does true sciatic neuritis occur? Biopsy and postmortem reports are unfortunately scanty. Hunt recorded a series of cases in which the sciatic nerve was thickened and edematous, and on section showed vascular engorgement and inflammatory exudate between the perineurium and the endoneurium. The changes

were not marked. Denny Brown reports the case of a woman with disseminated sclerosis, who developed sciatica. She collapsed and died while having an oxygen injection around the nerve. At autopsy the sciatic nerve on the right side was swollen over the whole of its course from the sciatic notch to the popliteal region and the blood vessels were noticeably engorged. There were no signs of adhesions or other fibrous tissue changes. A small piece of the nerve was made available by the Coroner for section. Nothing abnormal was seen in the low power view. Under high power it was seen that the vessels were engorged and there was lymphocytic infiltration around some small venules. The perineurium around some of the nerve fibers was lifted up by an exudate. The nerve fibers themselves appeared to be intact.

This is the pathology of acute interstitial neuritis. It would produce severe pain and marked tenderness over the course of the nerve with fasciculation and wasting. Although this type of case is seldom seen in surgical practice it is fully described by physicians (Walsh, Cohen) and is referred to as "true sciatica." Complete recovery after a few weeks of conservative treatment is not uncommon. Cohen points out that true sciatica sometimes presents the characteristics of a febrile illness, having a sudden onset, with a raised temperature during the first few days.

The functional element in sciatica. A functional element is present in many cases of sciatica. The purely functional cases and the malingerers are rare. However many patients who have true sciatica with an organic basis develop, for one reason or another a functional "overlay" which makes the pain worse, obscures the diagnosis, makes the condition persist, and impairs the chance of successful treatment.

CLINICAL EXAMINATION

The diagnostic possibilities thus briefly reviewed must be considered in the light of a careful clinical examination which may be conveniently carried out on the following plan:

History

Lumbar spine—shape, mobility, and tenderness in the back and the lower limb trigger points

Lasègue's sign

Wasting

Motor power

Tendon reflexes

X-ray examination

Rectal examination

Focal sepsis

W R.

Fig. 12. Right sided sciatica. On bending forward the spine deviates toward the painful side. At operation a "concentric disc" (lumbosacral) was found.

Urine

Lumbar puncture

History Pain in the back described by the patient as lumbago is almost invariable. It may precede or be coincident with the sciatic pain. The backache may be fibrositic in origin; it may be caused by degenerative changes in, or injury to, an intervertebral disc, or it may be associated with spinal arthritis.

The prevalence of injury as a causative or precipitating factor has been stressed too much in recent literature. Only a relatively small proportion (13%) of proved cases of prolapsed disc in our series had a history of injury definite enough to be held responsible. It seems probable that injury may precipitate the prolapse of an already degenerate disc, but only a very severe injury could possibly cause prolapse of a normal disc. Friberg has shown experimentally that the normal intervertebral disc is capable of withstanding without damage, very severe strain. In a fresh cadaver he punched a hole in the annulus of a lumbar disc. No prolapse occurred, nor did any appear after repeated violent movements of the spine or after great axial pressure. Moreover, when the cut was deepened to the nucleus itself and a prolapse had appeared, its size was not affected or only very slightly by movements of the vertebrae.

The influence of trauma in the production of prolapsed disc is, of course, an important medico-legal point. Trauma can be only a precipitating factor, i.e., an injury can cause a prolapse only if the disc is already degenerate.

Fig. 13. Fixed lumbar lordosis associated with right sided sciatica and spinal arthritis.

On the other hand, there appears quite often to be a definite connection between exposure to adverse climatic conditions and the onset of lumbago and sciatica. Sleeping out on wet ground, working in the rain and cold, or sitting on wet or cold surfaces, often precipitates the first attack, presumably of a fibrositic type.

Coughing, sneezing, heavy lifting and straining of any sort usually cause exacerbation of the sciatic pain, whatever the cause of the latter may be. No special diagnostic significance, indicating a prolapsed disc, should be attached to this symptom.

The state of the sphincters should be determined by careful questioning. Loss of control may indicate an intraspinal lesion.

The history of the previous attacks and their duration may help in the prognosis and may be a guide to treatment.

The lumbar spine. The back should be examined with regard to shape, mobility and tenderness. The range of movement of the lumbar spine is tested systematically. Some limitation is nearly always observed, ranging from slight stiffness to absolute rigidity. Extension is tested by making the patient lean backward from the erect position; flexion by bending forward in an attempt to touch his toes with the knees straight. The latter move-

Fig. 14. A typical disc spine with left sciatica. There is lumbar kyphosis and slight spinal list to the right. The spine is almost rigid. At operation a congested disc (lumbarosacral) was found.

Fig. 15. A typical disc spine with left sided sciatica. Note spinal list to the right. The spine is almost rigid. The scar of an unsuccessful Ober's operation is seen. On laminectomy a degenerate lumbarosacral disc was found.

ment may be limited either by a true stiffness of the spine or by a painful spasm of the hamstrings. To differentiate between the two the movement of flexion is next tested with the patient sitting on a couch the knees and the hips being flexed to relax the hamstrings. Lateral flexion is estimated by asking the patient to bend sideways from the erect position.

Only rarely (in cases of low sciatica) will the shape and mobility of the spine be normal.

In mild cases of the fibrositic variety there is frequently an associated postural defect—usually a hollow back the lumbar lordosis being increased. In such cases the spine is mobile although movement may be painful.

When the sciatica is caused by protrusion or degeneration of a disc, by hypertrophy of the ligamentum flavum or by spinal arthritis, gross deviations from the normal shape of the spine are observed and the spine may be stiff.

1. A common abnormality is a lateral deviation of the spine which appears only during flexion. When the patient stands upright his spine is straight, but on bending forward the spine deviates to one side, toward or away from the side of the sciatica (Fig. 12).

2. There may be a fixed exaggerated lordosis. The lumbar spine is stiff and moves en bloc when the patient bends forward spasm of the erector spinae muscles being visible and palpable. The movement of flexion takes place only at the hips.

This type of spine is commonly produced by spinal arthritis (Fig. 13).

3. The flat or kyphotic lumbar spine, sciatic scoliosis, and alternating scoliosis are usually due to abnormalities of an intervertebral disc or ligamentum flavum. In the case of a flat lumbar spine the lumbar lordosis is obliterated and the spine is very stiff. In the kyphotic lumbar spine the deformity has progressed a stage further the lumbar curve being reversed (Fig. 14). In the sciatic scoliosis we have a flat or kyphotic lumbar spine which also deviates to one side, usually away from the side of the sciatica, but sometimes toward it (Fig. 15). The lateral deviation starts from a low level, at the lumbarosacral junction or just above it, and from this point the spine leans sideways. It is a list to one side rather than a rounded curvature of the sort usually associated with the word scoliosis. The deformity is fixed. Extension is severely limited. The lateral inclination cannot be overcome either actively or passively. Attempts to straighten the spine are painful. The deformity persists when the patient lies down. Under anesthesia the lateral deviation disappears but if there is an associated lumbar kyphosis, this usually persists. Alternating scoliosis is rare. In these cases there is a sciatic scoliosis, but the lateral deviation varies in direction from time to time. For instance the change from one side to the other may be produced when the patient bends forward (Figs. 16 and 17).

cried and sobbed together. In succeeding months he became absorbed in the mysticism of the Bible, and, as "Ambassador of God" importuned the Pope for another crusade to free the Holy Sepulchre from the infidels. His sense of persecution grew stronger and stronger. If this was tertiary syphilis, it would indicate a more rapid progression than usual, for it was only about eight years since the first voyage on which the primary infection may be said to have occurred. However this would coincide with the rapid action of the spirochete in a member of a completely non-immunized group. Diagnosis is difficult, because of the chaotic mass of controversial material, but a detached historical spirit recognizes that, apart from the ophthalmia and the rheumatoid arthritis, syphilis would account for all of his symptoms, both in their nature and in the relative times of their occurrence. To explain them otherwise means considering a list of single and distinct pathological conditions, including relapsing fever typhus or typhoid, rheumatic fever and valvular heart disease, followed by paranoia.

In the spring of 1502 Columbus began his fourth and last "farewell tour" of America. He wanted to find a strait through which he might sail west into Portuguese Asia. During most of the voyage he was too sick to leave his cabin. Cardiac dropsy added to the pains of arthritis made his life miserable enough without the hardships of exploration. Poor food and bad weather plagued his little fleet. Storms wrenched and strained his crazy worm-eaten ships as they wandered painfully among the keys and shoals he had named the Garden of the Queen. Mutiny blazed up in his crews. Shipwreck ran him aground on Jamaica, where the Nazi-like conduct of his men started the first American Revolution. Only his ability to foretell an eclipse of the moon saved him and them from the revenge of the superstitious natives.

Arriving in Spain two years later he was so ill that he had to be carried ashore. Meanwhile, friend Isabella had died of an intestinal tumor untreated because she was too modest to allow herself to be examined. Her scamp of a husband, Ferdinand, always hostile, was of no help to the

discoverer of Spain's new empire. Poor Columbus lived in misery attempting to follow the court on its interminable peregrinations. Unable to endure the jittery paces of the Andalusian horses, he was forced to hoist his swollen legs on mule-back or be carried in litters.

Valladolid lies in a cleft among barren, treeless mountains, a city drowsing away the hours in its silent convents and dusty streets. There, heart sick and weary Columbus dragged himself after the court for the last time. There he lingered painfully until May of 1506 when his diseased heart valves finally played themselves out. He handed over into the hands of God his proud, courageous spirit.

A battered, wrecked old man,
Thrown on this savage shore, far far from home
Pent by the sea and dark rebellious brows
My terminus near
The clouds already closing in upon me,
The voyage balk'd, the course disputed lost,
I yield my ships to Thee

Walt Whitman.

Fig. 16. A case of right sciatica with alternating scoliosis. In the erect position the spine deviates to the left. During flexion the spine deviates to the right. Note the wasting and loss of tone in the right buttock. At operation a "concealed disc" (lumbosacral) was found.

It is probable that each of these deformities represents a mechanism designed to protect the nerve roots from pressure. There are several factors to be considered. Thus, extension of the spine diminishes the size of the intervertebral foramina by elevating the inferior articular process at each joint, and so may increase the sciatic pain. But, extension of the spine also relaxes the nerve roots and meninges, and so it may relieve the pressure on a nerve root or permit the nerve to slide into a less vulnerable position. For instance one of our patients could obtain relief only by lying on her face, i.e. by extending her lumbar spine. Again, flexion of the lumbar spine (lumbar kyphosis) tends to throw into prominence the protrusion of a disc—an undesirable effect but at the same time it increases the size of the intervertebral foramina and for this reason may be a position of ease. Contralateral scoliosis similarly has a dual effect. It increases the size of the intervertebral foramina on the painful side but also increases the tension in the nerve roots on that side. Ipsilateral scoliosis, on the other hand, diminishes the foramina on the painful side, but also relaxes the nerve roots on that side. The clinical result thus depends upon the balance of opposed factors and differs from case to case and in some instances from time to time in the same case (alternating scoliosis).

Tenderness in the back is variable. In functional cases there is widespread exaggerated ten-

Fig. 17. The same case as in Figure 16, after operation. A laminectomy with ample bone removal was performed. A "concealed disc" was exposed but no disc material was removed. The spinal deformity has disappeared and the sciatic pain is cured.

derness which disappears when the patient's attention is distracted. In fibrositis, with which a functional element is frequently associated the tenderness is similar.

Localized tenderness over a spinous process, an interspinous process, or an interspinous interval may be a guide to the level of a prolapsed disc but this sign is unreliable.

Nearly always there is localized tenderness over the sciatic notch, but apart from this tenderness in the leg is uncommon. Pressure over the tender area in the buttock may cause radiation of pain down the back of the thigh but trigger points elsewhere are unusual.

Lasègue's sign Stretching the sciatic nerve increases the sciatic pain and serves as a measure of the severity of the sciatica. The test is performed with the patient lying supine on a couch. With the knee kept extended the affected leg is lifted off the couch. In severe cases the hip flexion is resisted by muscle spasm when the movement has progressed through only 10 or 20 degrees. In mild cases an arc of 70 or 80 degrees is permitted. Flexion of the sound limb in many cases causes either a pain in the lower back or an accession of sciatic pain in the affected leg presumably because this movement stretches the structures in the lower back, including the nerve roots on both sides. Ingenious attempts have been made, by modifying the straight leg raising test to differentiate between the various causes of sciatica.

The "head and knee" test described by Young is an example. These refinements have little clinical value.

Wasting may be apparent in the buttock, thigh, or leg. The distribution of the wasting may give some indication of the level of the lesion. If the first sacral root is affected, wasting of the outer buttock (gluteus medius) and of the calf follows, and the ankle jerk is lost. Interference with the fifth lumbar root causes wasting of the anterior tibial compartment, and the ankle jerk is spared.

Loss of power Actual loss of muscle power is rare, but an apparent loss of power is often seen, because muscle effort is painful and therefore voluntarily limited. Note that muscle power should be tested with the patient standing as well as lying. A slight weakness of the calf muscles, for instance, is best detected by asking the patient to stand on tiptoe.

Abnormalities of sensation. Subjective disturbances (paresthesia or a feeling of numbness) may be the first symptom of sensory impairment. Hyperalgesia and hyperesthesia may occur. Later actual sensory impairment (light touch, pinprick, postural, or vibration sense) may be found. Although the delineation of the dermatomes is uncertain, and more than one root must suffer significant damage before sensory loss is observed, yet a careful study of the sensory changes may help to localize the responsible lesion (Bradford and Spurling, Pennybacker, Kellgren).

The fifth lumbar root territory includes the dorsum of the foot and the big toe. The first sacral root supplies the outer side of the foot and the outer two toes.

Tendon reflexes. The knee jerk depends on the second, third, and fourth lumbar segments. It is not, as a rule, affected in cases of sciatica. It may actually be enhanced if the tone of the hamstrings is impaired. The ankle jerk is frequently lost or depressed. It depends upon the roots of the fifth lumbar, first sacral, and possibly the second sacral nerves. According to Bradford and Spurling the ankle jerk is affected in 30 per cent of lumbosacral disc prolapses, and in 25 per cent of fourth lumbar disc prolapses, but it must be noted that the ankle jerk may also be affected by a prolapse at a higher level. The ankle jerk is also lost in cases of interstitial neuritis of the sciatic nerve.

Once lost, the ankle jerk may not return, although the sciatica may be cured. An absent ankle jerk does not necessarily indicate active sciatica. It may be the relic of a previous attack.

X-ray examination of the lumbar spine and pelvis is an essential part of the examination of all cases of sciatica. The lateral view should be

centered on the fifth lumbar vertebra because the majority of the vertebral lesions which may cause sciatica occur in the lower part of the lumbar spine.

Contrast roentgenography is still used in some clinics for the diagnosis of disc protrusions.

Adverse effects after the injection of iodized oil have frequently been recorded. Verbruggen reports pain in the legs, backache, nausea, vomiting, retention of urine, pyrexia, meningismus, and an increased cell count in the cerebrospinal fluid. Marcovitch and Walker report pyrexia, vomiting, stiffness of the neck, and increase of cells and protein in the cerebrospinal fluid. They report a fatal case in which, at postmortem, acute meningeal reactions were found in the spine and around the brain stem. Sicard and Forestier noted a brief pleocytosis. Globus found a variable pleocytosis, but there were no adverse effects clinically. Lindblom noted a pleocytosis and positive Nonne and Pandy tests, these signs disappearing within a month. Klose and Peiper reported transient headaches, but no other ill effects. MacLachlan, Wartenberg, Sharpe and Peterson, Bergerhoff, Nonne, Fumarola and Enderle, Donat and others, also found adverse clinical and pathological changes after the use of iodized oil in the theca. Experimental work in animals has produced similar results (Brucker and Propper, Davis, Haven, and Stone, and Ayer and Mixer).

In 2 of our cases in which lipiodol had been used the roots of the cauda equina were, at operation, seen to be matted together by a yellow fibrous exudate. The meninges were thickened and infected. These pathological changes were attributed to the use of lipiodol. The patients suffered no permanent harm. Of a further 8 cases in which lipiodol was used and not removed, 2 were made permanently worse (the sciatica was permanently exacerbated) but the remaining 7 presented no immediate ill effects. Two years later 3 of the 7 were traced and no ill effects had appeared.

Thus it is clear that lipiodol may cause pathological changes in the meninges and nerve roots, but permanent harm is unusual. With pantopaque or with air there is little risk, but the really important fault of contrast roentgenography is its unreliability remains. With proper roentgen technique a large protrusion would doubtless be revealed by contrast roentgenography in every case. However in such cases the diagnosis is easily made and the level of the lesion may be determined by clinical examination. On the other hand, a small protrusion, a "concealed" disc, a degenerate disc which is not protruding, and even a disc protruding to a fair degree in a lateral situation, will not

be shown by contrast roentgenography. In other cases contrast roentgenography may falsely indicate a protrusion which does not really exist. Fortunately the plain roentgenogram often indicates the presence and the level of a degenerate disc. Very slight narrowing of a disc space may be significant if taken in conjunction with the history and physical signs.

Rectal examination must be made in every case of sciatica. It is a simple and almost certain method of excluding pelvic neoplasm from the diagnosis.

Focal sepsis As previously mentioned, focal sepsis may aggravate a case of sciatica and impair the chance of successful treatment. It is as well, therefore, to examine the teeth, tonsils, and sinuses. In severe cases, and particularly when operative treatment is being considered, the erythrocyte sedimentation rate should be determined. This factor may indicate concealed focal sepsis. Occasionally removal of a septic focus is followed by complete and permanent cure of the sciatica.

Lumbar puncture. The protein content of the cerebrospinal fluid is sometimes raised in cases of prolapsed intervertebral disc.

The cerebrospinal fluid was examined in 39 cases in which a prolapsed disc was subsequently found at operation. Only 13 of these presented an increased protein content. In most of them the elevation was moderate from 50 to 80 mgm. per cent. In 1 case the elevation was 200 mgm. per cent.

In 12 of the 15 cases in which the thickened ligamentum flavum was responsible for sciatica, the cerebrospinal fluid was examined. The protein content was raised in 6 of these.

So far as the question of a prolapsed disc is concerned, a raised protein content supports the diagnosis, but a normal result does not exclude it. We no longer perform this test as a routine procedure.

DIFFERENTIAL DIAGNOSIS

This is often difficult and sometimes impossible.

In the type of sciatica caused by lumbar fibrositis there is a history of one or more attacks of lumbago preceding or associated with the sciatic pain. There is widespread tenderness in the lower back. The lumbar spine may be moderately stiff but it is not deformed. There is no loss of motor power in the affected leg and no sensory loss. The ankle jerk is unaffected. Thus, in the typical case, there is no loss of conduction in the affected nerve.

Points may be present, but they are rare. A roentgenogram of the spine shows no significant

abnormality. Speaking generally fibrositis gives rise to many symptoms but few signs. In this type of case, particularly there is frequently a functional element which makes treatment unsatisfactory.

The diagnosis of spinal arthritis is suggested when the patient is over 40 years of age and has a stiff spine with spasm of the erector spinae muscles and a fixed lumbar lordosis. The roentgenogram may support the diagnosis. Signs of interference with conduction in the affected nerve roots may or may not be present. If the arthritic joints are producing referred pain there is no loss of conduction but a severe arthritis may provoke inflammatory changes around the root sufficient to interfere with conduction and produce abnormal neurological signs, usually of a minor degree (73). Differentiation between spinal arthritis and prolapsed disc may be impossible without an exploratory operation. Lumbar puncture may be done in doubtful cases. A raised protein content would favor the diagnosis of prolapsed disc, but it should be noted that according to Putti (73) the protein in the cerebrospinal fluid may be elevated in the neighborhood of an arthritic lateral joint.

Some cases of prolapsed disc and thickened ligamentum flavum are easily recognized. For instance, a young man develops sciatic pain soon after injury or strain of the back. On examination the lumbar spine is seen to be rigid and deformed. The normal lordosis has been lost the spine being either flat or kyphotic, and there may also be a lateral deviation, sciatic scoliosis. There is some wasting of the leg, some loss of muscle power and some sensory loss. The ankle jerk is absent. The roentgenogram may show narrowing of a disc space. The sciatica is caused by a prolapsed or degenerated intervertebral disc, by a hypertrophied ligamentum flavum, or by both.

In typical cases of this sort, it is not difficult to decide the diagnosis and advise appropriate treatment. Unfortunately there is a considerable number of patients with equivocal physical signs. A prolapsed disc or hypertrophied ligamentum flavum may produce signs which are not striking stiffness being only moderate and deformity absent, and there may be no interference with conduction in the nerve. The roentgenogram may give no assistance. The protein in the cerebrospinal fluid may be within normal limits. It is also to be noted that prolapsed discs may (rarely) occur in the middle-aged and elderly as well as in the young and that the history as regards injury is not a reliable guide.

Clearly there are ample possibilities of error in diagnosis. However there is usually some pointer

Laminectomy revealed neither a prolapsed disc nor a thickened ligamentum flavum. On opening of the dura the nerve roots of the cauda equina were matted together with a yellow exudate. (This was one of the cases in which the lipiodol had provoked a reaction.) There was also a misleading appearance of a filling defect.

The immediate result was that the patient was cured of all pain. A year later there was no pain at all. The patient said that his back felt weak. There was slight weakness of the peroneal (right) also hypesthesia of the outer part of the dorsum of the right foot.

Case 3. Male, aged 33 years. For ten years, on and off he had had sciatica on the right side, which had become worse since he lifted a heavy weight 5 years ago.

The dorsal kyphosis had increased there was spasm of the erector spinae and flexion of the lumbar spine was limited, extension was limited and painful there was tenderness over the fourth and fifth lumbar spines, and over the right sacroiliac joint the Lasègue sign was positive on the right side at 40 degrees, the right calf was wasted there was hypesthesia to pin prick on the posterolateral aspect of the right thigh and outer part of the right calf vibration sense was absent over the right tibia, the postural sense of the right toes was impaired, the right ankle jerk was absent the roentgenogram showed no abnormality. The lateral joints were all in the coronal plane and therefore not clearly visualized.

Right hemilaminectomy was done. There was no abnormality of the intervertebral discs or the ligamentum flavum. A spinal arthrectomy was performed on the right side.

The immediate result showed much improvement with no pain, the sensory signs had disappeared.

Fifteen months later the patient was cured. There was no neurological abnormality and only occasional backache.

Case 4. Male, aged 30 years. He had had sciatica on the left side for 9 months.

The lumbar spine was stiff. There was tenderness over the third and fourth lumbar spines. The Lasègue sign was positive on the left at 50 degrees. There was marked loss of power in the dorsiflexors of the left foot. The protein content of the cerebrospinal fluid was 25 mgm. per cent. The roentgenogram showed anomalies of articular tropism. There was osteoarthritic lippling of the lumbar vertebrae.

Hemilaminectomy on the left side showed no abnormality of the intervertebral discs or ligamentum flavum. A spinal arthrectomy was done on the left side. (At operation the lateral joints on the left side appeared to be subluxated.)

The immediate result was a complete relief of pain. Later there was no sciatic pain but a little backache from time to time.

Evidently the intervertebral disc is not the only factor to be considered.

In Table II the diagnoses made in the 249 consecutive cases are shown. In this series, there were 129 cases with neurological abnormality. Table III shows the diagnoses made in this group. It will be seen that there were 54 cases in which the diagnosis was doubtful. It is the fashion now days to dispose of these cases by saying that they must all be protruded discs. This view is incorrect, as shown by the operations described previously.

Of the 54 cases undiagnosed, some, we may suppose were disc lesions others no doubt were

caused by lateral joint arthritis, and there may also have been other factors not yet elucidated.

TREATMENT

Certain methods of treatment and the results obtained will now be described.

In an acute attack of sciatica the pain may be agonizing and may continue at this pitch for days and even weeks.

Palhative Treatment

1 Complete rest in bed. The patient is allowed to lie in whatever position he finds most comfortable. The long Liston splint, which is sometimes advised, does no good because the patient will not tolerate it when tightly applied and a loosely bandaged splint soon becomes merely an irritating appendage which prevents him from finding a comfortable position. Skin traction is also recommended by some writers. In my experience it gives no relief. The best plan is to support the patient with pillows in whatever position he obtains most relief from pain. Skillful nursing is obviously most important in this respect. A well sprung mattress should be provided.

2 Analgesic Drugs. For severe cases morphia will be required. When the pain becomes less intense, cachets containing pyramidon (gr 5) medinal (gr 3) and codain (gr 3/4) (Harris) are useful, and at a later stage aspirin and phenacetin may be used. Medinal (gr 7 1/2) may be given at night.

3. **Local applications.** The affected limb should be painted with liniment methyl salicylate, with glycerine and belladonna, or with lead and opium lotion, and wrapped loosely in cotton wool.

4. **Radiant heat or diathermy** may be applied daily. Massage should not be used. Light massage is useless, and deep massage is too painful.

5. **Care of the bowels.** This may be difficult. Aperients should be given if the patient is constipated. If the pain is severe, he will not be able to use a bed pan and will have to be lifted out of bed to a commode.

6. **Oxygen injection into the affected limb,** as described by Martin is a local measure which is useful in the acute and subacute stages of sciatica, although it is difficult to see why it should be so. It undoubtedly gives dramatic relief in many cases. The oxygen is bubbled slowly from a "Sparklet" containing 1 liter or from an ordinary oxygen cylinder with a fine adjustment valve, through warm water and it enters the thigh through a Record needle $\frac{3}{16}$ mm. in diameter which is introduced subcutaneously. Sterilized rubber tubing is used. The injection is continued until the thigh is moderately ballooned by the gas. If the pain returns, the injection may be repeated.

The treatment of chronic or recurrent sciatica is based as much as possible on the cause of the pain. In our series there were 15 cases which were thought to be due to fibrositis of the buttock and thigh. They were treated empirically by attention to focal sepsis, by physiotherapy, by stretching the sciatic nerve, and by perineural injection of saline solution. These measures gave temporary relief but there were no cures. The symptoms persisted for months and in some cases for years.

Perineural injection. The surface marking of the exit of the sciatic nerve from the pelvis is at the junction of the middle and outer thirds of a line joining the posterior superior spine of the ilium with the tip of the great trochanter. This is also, as a rule, the point of maximum tenderness. In making a perineural injection, the needle is inserted at this point and is pushed gently in until it touches the sciatic nerve. The surgeon can tell when the sciatic nerve is reached by the twitching of the foot which is instantly provoked. When this occurs, the needle is withdrawn a little and from 80 to 100 c.c. of normal saline solution

to balloon the intermuscular spaces in which the nerve is lying and so to disrupt the adhesions around the nerve. Perineural injection is an uncertain method of treatment, but it is harmless and sometimes produces good results.

Stretching the nerve. While the patient is anesthetized, the sciatic nerve is stretched by flexion of the hip, the knee being held in full extension and the ankle in full dorsiflexion. The flexion of the hip should be forced as far as possible, short of dislocating the joint. "Adhesions" may be heard to give way in the thigh during this maneuver.

For sciatica caused by lumbar fibrositis, rest, physiotherapy, and attention to focal sepsis are the first steps in treatment. For severe or moderately severe cases, complete rest in bed should be insisted upon. If the pain still persists, an epidural injection should be tried and this may be combined with manipulation of the spine.

Sciatica caused by spinal arthritis, prolapsed intervertebral disc, or thickened ligamentum flavum is treated first of all by rest. The patient is confined to bed for 3 or 4 weeks. If during this time there is significant improvement this conservative line of treatment is continued, and in some cases proves successful.

Case 1. Male, aged 46 years. He had very severe left sciatica for 6 months.

The lumbar spine strongly indicated disc lesion. There was marked kyphosis and list to the right. The spine was very stiff.

The Lasègue sign was positive on the left side at 90 degrees. There was marked wasting of the left thigh and calf and general weakness of the left leg. There was no sensory loss. The left ankle jerk was absent. The protein content of the cerebrospinal fluid was 150 mgm. per cent. The roentgenogram showed no significant abnormality.

With complete rest in bed the patient rapidly improved. He was kept in bed for 3 months. The pain disappeared. Eighteen months later he wrote to say that he had no sciatic pain. His back felt weak, but he had been able to resume his work as a bank clerk and had been able to work in his garden in his spare time.

This was almost certainly a prolapsed disc.

Case 2. Male, aged 52 years. Six months before his first attendance he fell heavily on both buttocks and subsequently had persistent lumbar backache, which after 2 or 3 months began to radiate into the back of the right thigh and calf. When first seen, 3 years ago, he had severe right sciatica.

no spontaneous pain. Slight aching pain in the lower back and in the back of the right thigh occurred after exercise. The Lasègue sign was negative on both sides. There were no abnormal neurological signs.

This sciatica was probably caused by arthritis of the lateral joints.

It is advisable to give rest a trial, even in cases with physical signs of an intraspinal lesion. Operation should be considered only after prolonged rest in bed has been tried and has failed, unless the presence of severe symptoms forces the surgeon's hand. The tedium of the stay in bed is beguiled daily with physiotherapy and the usual clinical, laboratory and x-ray investigations are performed without undue haste, over a period of 2 or 3 weeks. By this time it will be possible to decide whether continued rest is likely to produce an improvement. Some patients improve up to the point where by a careful regime, avoiding exposure and excessive strain, they can be kept fairly comfortable and fit for business.

In some cases, pain disappears suddenly. For instance one of our patients with chronic sciatica suddenly became free from pain as she was stepping out of her bath one morning. She said she felt that something had moved in her back.

Sudden improvement may occur because the nerve root involved has moved into a position less exposed to pressure, or the protruding part of the disc may have separated completely and moved away from the root on which it was pressing. This had happened in 1 of our cases, in which a fragment the size of a pea was found completely detached, in the epidural space, over the body of the fifth lumbar vertebra.

If rest produces no significant improvement epidural injection, combined in some cases with manipulation of the spine is the next line of treatment. If the pain still persists, the question of operation arises, and will be decided by the age and general condition of the patient, his occupation, and the degree of disability. For some individuals a spinal support is the best treatment.

Epidural injection. Pentothal anesthesia is used. The patient lies on his side. The cornua of the sacrum are identified and the posterior surface of the coccyx palpated below them. A Labat's needle is inserted horizontally between the cornua and directed headward and slightly forward. The needle will enter the canal of the sacrum without any difficulty. It is pushed in for about an inch. With a Labat's 20 c.c. syringe with a two-way attachment, a large volume of normal saline solution, previously warmed to blood heat, is injected. As a rough guide 250 c.c. are taken as the correct volume. It is necessary to use a large volume because the fluid acts mechanically. As the injection

proceeds it fills first the sacral canal, and then is forced upward into the lumbar canal outside of the dura. As more fluid is injected and the pressure inside the canal increases, the fluid escapes laterally through the intervertebral foramina and in doing so it disrupts any adhesions which have formed around the nerve roots, e.g. in association with arthritic changes in the lateral joints. That is the supposed rationale of the injection. Sometimes there is ocular proof that the fluid has in fact escaped through the intervertebral foramina, as a swelling appears under the erector spinae muscle on one or both sides. A considerable degree of force is necessary to impel the fluid up the canal and the injection is usually a laborious and tedious business. Morphine may be required the first few hours after the injection.

There are two possible errors in making this injection. The needle may be put in too near the surface and so lie on the posterior aspect of the sacrum instead of inside of it. The operator will detect this error at once because the first syringe-ful will produce a swelling over the sacrum. The second error is to push the needle in too far so that it enters the dural sac. This will not happen if the needle is inserted only 1 inch.

This injection is worth trying because it is harmless and sometimes produces a dramatic and lasting cure. Some diagnostic importance has been claimed for the epidural injection in that it is said to cause an exacerbation of the pain from a prolapsed intervertebral disc. We have not found this to be the case.

Manipulation of the spine is performed under pentothal anesthesia. If combined with epidural injection it should be done first, while the relaxation is complete. The method described by Bankart is used.

There are four movements to be carried out namely

1 Flexion. The surgeon stands on the right hand side of the supine patient, and places his right arm under the patient's knees. He lifts the legs up flexing the hips and knees, and carries the knees upward until they are pressed on the patient's chest. The fullest possible flexion of the lumbar spine is thus obtained.

2 Rotation to the left. The patient lies on his right side. The left leg hangs over the side of the table, and the left arm is placed behind the patient's back. The surgeon leans with his right forearm on the left iliac crest, while with his left hand he grasps the left shoulder. A forcible rotatory movement of the sacroiliac joint is produced by pulling the iliac crest forward and pushing the shoulder backward.

Fig. 18. Lines of bone section for the operation of spinal arthroctomy

3. Rotation to the right. The surgeon goes to the other side of the table and the patient is turned on to his left side. The maneuver described above is repeated.

4. Extension. The patient is turned on to his face. With his left arm the surgeon lifts the patient's legs until they are almost vertical, and with his right hand presses downward over the lumbar spine, extending it as much as possible.

The manipulation is followed by a course of spinal exercises, radiant heat and deep massage.

Most patients with sciatica have stiff spines, and manipulation of the spine as an empirical method of treatment was much employed when prolapsed intervertebral discs were less frequently diagnosed. It is now in disfavor because it has been said that manipulation may make an unsuspected prolapse worse, and perhaps even precipitate a paraplegia. We have never seen any ill result from the operation and have heard of only one, in a patient who developed sensory loss in the leg and foot immediately after a manipulation of the spine (Dick, 1943). Friberg has shown experimentally that the most powerful flexion or extension of the lumbar spine has no effect on artificially produced prolapses. The risks of manipulation are evidently small. We still think it is worth trying a manipulation, except in those cases which have the typical signs of a prolapsed disc.

Operative Treatment of Sciatica

The operations to be considered are spinal arthroctomy and laminectomy. (We have seen 5 cases in which Ober's (66) operation had been per-

formed elsewhere. The result in each case was unsatisfactory.)

Spinal Arthroctomy This operation was mentioned by Putti (73). It has been elaborated and extensively used by Bankart.

The steps of the operation are as follows (Figs. 18, 19, 20).

1. A midline incision is made over the lower 3 lumbar spines and the upper part of the sacrum.

2. With a sharp chisel, the erector spinae muscles on each side are reflected from the spinous processes, throughout the length of the incision.

3. On the affected side, the reflection is continued laterally until the lateral joints L 3 and 4, L 4 and 5 and L 5 and S 1 are exposed. The end of a Bristow elevator is placed on the outer side of each joint to act as a landmark and retractor. These joints are dealt with separately in the following manner.

4. The inferior articular process of the upper vertebra is isolated by cutting through the lamina with an osteotome or with Lane's gouge forceps.

5. This articular process is removed with Lane's gouge forceps.

6. The base of the superior articular process of the lower vertebra is cut through with an osteotome.

7. This articular process is removed with Lane's gouge forceps.

What is the principle of the arthroctomy operation? How does it work? It was originally designed to cure sciatica by removing the lateral joints, on the assumption that these arthritic joints were causing sciatic pain. But clearly there are other

Fig. 19.

Fig. 19. Spine after spinal arthrectomy. The joints between L4 and 5 and L5 and S1 on the right side have been removed. The black cord represents the fourth nerve root.

Fig. 20.

Fig. 20. Roentgenogram taken 4 years after spinal arthrectomy on the right side.

effects of arthrectomy. Every arthrectomy is necessarily also a hemilaminectomy. The lateral parts of the laminae and ligamentum flavum are excised, in addition to the lateral joints. The effect of this is to remove the posterior wall of the spinal canal on the affected side and also the posterior wall of the intervertebral foramen. If the diagnosis is mistaken and the sciatica is really caused not by spinal arthritis, but by a protruded disc (a lateral protrusion especially) or by hypertrophy of the ligamentum flavum, the environment of the nerve root may yet be altered sufficiently to produce a cure. In this connection it should be noted that the first step of the arthrectomy operation is an exposure of the laminae. It is a good plan to expose the corresponding disc at this stage. It is easily done by removing the ligamentum flavum and exploring the interlaminar space. If an abnormal disc is found this can be dealt with. If the discs are normal the arthrectomy is completed.

Laminectomy. In the modern operation for prolapsed disc only the necessary minimum of bone is removed, but I prefer to make a wide exposure and remove a considerable amount of bone on each side of the interspace. This allows a full view of the disc and nerve root and permits the surgeon to see clearly what he is doing. It also gives the nerve root a margin of safety from subsequent compression by a recurrent protrusion or by scar tissue. (In 1 of our patients [not included in the

present series] a protrusion was removed from the fourth disc through a narrow exposure, only a tiny portion of bone being removed from the lamina of the fourth lumbar vertebra. The pain, never completely relieved, soon returned and became worse than it had been before the operation. At the second operation, 6 weeks after the first, the only abnormality found was a dense mass of scar tissue which had formed around the fourth lumbar root. This was dissected out and bone was removed widely on both sides of the interspace. This relieved the pain completely.)

For laminectomy the patient lies on his side with the affected side uppermost.

1. A midline incision is made from the lower border of the third lumbar spinous process to the second sacral spinous process.

2. With a sharp chisel the erector spinae muscles are reflected on both sides. Packing is done at the same time.

3. The packing is removed and further dissection is done to expose the laminae and the ligamentum flavum.

4. The spinous process of the fifth lumbar vertebra is excised.

5. The ligamentum flavum between the fifth lumbar and first sacral vertebrae is excised. On the affected side particularly the lateral part of the ligament, which sometimes extends far outward and is in contact with the issuing nerve root (fifth lumbar) is dissected.

Fig. 2. Portion of intervertebral disc removed at the second operation in a case of sciatica. At the first operation a large protrusion of the fifth disc was found and a piece of disc material the size of a small cherry was removed. This operation gave complete relief from pain but the sciatica recurred after 3 years. At the second operation the material shown above was removed. This operation relieved sciatic pain, but backache persisted.

6. The interlaminar space is enlarged with Lane's gouge forceps, the bone being taken away in small bits from the contiguous margins of the fifth lumbar and first sacral laminae, until free access to the dura is obtained.

7. By blunt dissection and gentle swabbing with cotton wool pledgets, the dura and the fifth lumbar nerve root are exposed and cleansed, the nerve root will be seen coursing inside its dural sheath to the intervertebral foramen.

8. With a blunt hook, the root is gently retracted outward, and the theca is gently pushed inward with a Macdonald's retractor.

9. The floor of the canal, so exposed, is explored for a protrusion. If a protrusion appears, the overlying posterior ligament is incised and the loose portions of the disc are removed. When all that is loose has come away the surgeon should be satisfied. Nothing is gained by curettage or removal of the remainder of the disc. Removal of a prolapsed disc should mean removal of the loose portions only. Only the part that is loose should be removed, and no more.

10. Occasionally a midline protrusion can be felt, but it will not be properly exposed, by the steps described. In such cases, the dura should be opened. The protrusion is then excised transdually.

11. If nothing is found at the fifth interspace, the fourth interspace should be explored and if that is also normal, the third interspace should be explored. (The vast majority of protrusions occur at either the fourth or fifth interspace.)

Operation for concealed disc and degenerated disc without protrusion. We have referred already to the cases in which only a tiny protrusion (concealed disc) or a degenerated disc, not protruding, is found. There is clearly no question of relieving pressure on a nerve root, since no root is being pressed upon. If removal of disc tissue is attempted, it may be found that there is a little shaggy fibrous tissue in the superficial layers, but there is no loose material. In such cases we do not remove any material from the disc. I do not believe that biting out the disc tissue with a punch serves any useful purpose. Therefore, when the nature of the lesion has been verified, the incision is closed.

The results, immediate and remote, are less satisfactory in these cases of concealed disc than in those in which there is a definite protrusion. Relief from pain is slower and less complete. This is an important consideration in selecting cases for operation.

In the operation for a concealed disc a wide exposure, with ample resection of bone, is a valuable precaution, since a protrusion may occur subsequently if the degeneration of the disc progresses.

RESULTS OF TREATMENT

Follow up proved to be difficult and is incomplete. Due to war time difficulties many patients could not be traced.

The military cases were (with the exception of certain operative cases) excluded from the review of the results of treatment. Comparison of the results in civilian life with those in Service patients is seldom valid. The remaining cases totalled 206, as follows:

Cases treated by physiotherapy alone	19
Cases treated by manipulation of the spine and stretching of the nerve	25
Cases treated by epidural injection	37
Cases treated by open operation.	125
Total	206

1. Results of physiotherapy (19 cases). The average duration of attendance was 30 weeks. On follow up 3 years later 6 patients were symptomless, 6 still had pain, and 7 could not be traced.

2. Results of manipulation of the spine and stretching of nerve (25 cases). The average duration of attendance was 25 weeks (the manipulation being followed by physiotherapy).

There were no quick cures but most patients derived subjective benefit from the manipulation.

On follow-up 3 years later 5 patients were symptomless, 6 still had pain, and 14 could not be traced.

REVIEWS OF NEW BOOKS

BECAUSE the author of *Postgraduate Obstetrics* has had extensive experience as a teacher of postgraduate courses this book is distinctly authoritative. He has attempted to discuss only subjects which should be of interest to the average family doctor based on the statistical frequency of obstetric complications.

The chapter dealing with the toxemias of pregnancy is admirably presented and it emphasizes the conservative attitude of nearly all obstetricians as regards the treatment of eclampsia. However one does not agree with the author's statement that it is justifiable to state didactically that eclampsia *resembla a contraindicación a cesárea section* (author's italics). In rare instances a cesarean section under direct infiltration anesthesia is justifiable in the presence of eclampsia.

In the section on the acute infectious diseases, such unusual diseases as scarlet fever, measles, German measles, and malaria are discussed during the first three months of gestation. One has less faith than Mengert in cytography as an aid in the diagnosis of placenta previa. Many believe that the Braxton Hicks version which is described as one form of treatment of placenta previa should be given up entirely because it is a dangerous procedure even for specialists. On the other hand contrary to the author one believes that a cesarean section is indicated in all cases of total placenta previa, even if the baby is not viable or is dead, so as to prevent maternal death or injury.

One agrees that premature artificial rupture of the membranes represents the safest method of induction of labor provided the proper conditions are present but it is doubtful that when pituitary extract is used for induction as much as 6 minims can be used as one done with impunity. Rupture of the uterus has followed even 1 minim doses given for induction of labor. In the section dealing with uterine inertia Mengert properly warns that the use of more than 3 minims does impose intolerable maternal and fetal risks. In the discussion on postpartum hemorrhage one believes two recommendations should be omitted namely the use of the Crédé maneuver even if bleeding is not checked by oxytocic drugs and the use of intravaginal douches. There may be a question as to whether it is proper in a book on postgraduate obstetrics to include a detailed chapter on sterility including the matters of adoption of a baby and artificial insemination. Minor criticisms are the frequent use of the word "pituitrin" a trade name, instead of the term "posterior pituitary extract" and the secondary position (in parentheses) assigned to the metric system. The use of the metric system in dealing with medical subjects conforms with practically all foreign medical literature and many representative American journals.

In spite of suggested differences of opinion this book is a valuable contribution. It covers all the obstetric subjects with which general practitioners must be familiar. It is well written by one of the foremost obstetricians, it contains sound, practical advice and it has numerous instructive illustrations most of which are beautiful drawings by Ruth Maxwell Sanders. The book has been printed on paper of good quality the type is clear and the illustrations have been well reproduced.

J. P. GREENHILL

THE monograph *Penicillin in Neurology* devotes approximately one-half of its text to basic studies describing the dispersion and absorption of penicillin when injected intrathecally and to the effect of this drug upon normal nervous tissue. Four of ten chapters are concerned with penicillin therapy in meningitis in infections of the skull and brain, in diseases of the spinal cord and its coverings, and in syphilis of the central nervous system. A final chapter recounts briefly the relation of antibiotics other than penicillin to the normal and diseased central nervous system. Selected references 311 in total number are appended to each chapter. The authors may be considered as authorities since they were among the first if not the first, to report certain noxious influences of penicillin upon the intact and infected brain. These clinical observations have been followed by a series of lengthy and critical experimental investigations.

The textual material and the well chosen illustrations and charts, largely a summation of the authors own experiences combine to form a scholarly description of the biophysics of penicillin. The discussion of penicillin therapy suffer only from the usual need of terminating a modern monograph at some definite publication date and from the obvious fact that antibiotic therapy is a matter of daily accruing data. This deficiency is most noticeable in the chapter devoted to streptomycin, streptothricin, actinomycin, and clavacin.

The wisdom of including a chapter upon the value of penicillin in syphilis is open to the contention that this might be evaluated more clearly by contrast to other methods of therapy detailed in a specialized text upon syphilis. Neurologists and neurosurgeons should be very content with this monograph, however and make this edition and future editions mandatory reading for their students.

HARVEY WOODMALL

PENICILLIN IN NEUROLOGY. By A. Earl Walker, M.D. and Herbert C. Johnson, M.D. Springfield, Illinois: Charles C. Thomas, 1946.

POSTGRADUATE OBSTETRICS. By William F. Mengert, M.D. New York and London: Paul B. Hoeber Inc., 1947

3. Results of epidural injection. This was often combined with manipulation of the spine and was usually followed by physiotherapy.

In 14 cases with no neurological abnormality the average duration of attendance was 16 weeks.

In 1 of these cases there was complete relief of pain after the injection.

Most of the patients obtained considerable but not complete relief.

On follow up 3 years later 3 patients were symptomless, 6 still had pain and 5 could not be traced.

In 23 cases with abnormal neurological signs the average duration of attendance was 12 weeks.

Immediate results 9 patients were cured, 8 were benefited, 4 were not benefited, and for 2 no record was available.

On follow up 3 years later 12 patients were symptomless, 6 still had pain, and 5 could not be traced.

In 3 of the patients without symptoms the abnormal neurological signs and the spinal deformity and stiffness had disappeared.

Thus, altogether there were 37 cases treated by epidural injection, and in 10 there was immediate and lasting relief of pain.

On follow up of these 37 cases 3 years later, 15 of the patients were symptomless, 12 still had pain, and 10 could not be traced.

The results of epidural injections are noticeably better in the group with abnormal neurological signs, as might be expected. Epidural injection is certainly worth a trial as it is harmless, it nearly always gives some relief and in a proportion of cases it produces a complete cure.

4. Results of operation (125 cases). There were 55 arthroplasties and 70 laminectomies.

Arthroplasties (55 cases). Detailed records of the state of the lateral joints excised in these operations are not available. In some cases there was gross arthritis in some there was subluxation of one or more joints in a proportion there was no macroscopical abnormality.

Immediate results 39 patients were completely cured, 3 were benefited and 13 patients were not benefited.

Of the 39 cured patients 25 remained symptomless, 10 had recurrence and 4 could not be traced.

Three of the patients with recurrence subsequently had an exploratory laminectomy because the pain persisted. In all 3 a thickened ligamentum flavum was removed.

The results of these 3 operations showed that 1 patient was cured 1 was benefited, and 1 had no benefit whatsoever.

Fig. 22. Roentgenograms of the case referred to in Figure 21. The preoperative roentgenogram was normal. The first operation was performed in 1941 and the second in 1943. Note progressive narrowing of the disc.

In 2 cases the recurrence was on the opposite side. In 1 of these a further arthroectomy on that side was performed which cured the recurrence.

Follow up of the 3 patients who were benefited showed that 1 was cured, 1 was still having pain and 1 could not be traced.

Follow up of the 13 patients on whom the operation was a failure showed that 1 had recovered, 1 was cured by subsequent spinal fusion, 1 was cured by injection of the nerve, 1 was cured by removal of the ligamentum flavum 6 were still having pain, and 3 could not be traced.

Thus, of the 55 patients, at the follow up 2 to 3 years later 30 were symptomless (5 of these having had other treatment since the arthroectomy) 17 still had pain, and 8 could not be traced.

A complete and lasting cure, apparently attributable to the arthroectomy was obtained in 25 of the 55 cases.

Laminectomy (70 cases). The operative findings were as follows:

a. Abnormal intervertebral disc with or without associated thickening of the ligamentum flavum (40 cases)

b. Thickening of ligamentum flavum (no prolapse of disc) (14 cases)

c. No pathology discovered in disc or ligamentum flavum (15 cases)

d. Spondylolisthesis (1 case)

a. Abnormal intervertebral disc (40 cases) civilian (23 cases) and military (17 cases)

The immediate results in the civilian case showed that 21 patients were cured 1 patient was benefited, and 1 was not benefited.

malignant neurogenic melanoma, arising from the Schwann cell and the nerve cell (8) benign and malignant neurogenic melanoepithelioma, from the pigment epithelium of the retina and ciliary body (3) leiomyoma, from the dilator and sphincter muscles of the iris, (4) dictyoma, from the pigment epithelium of the iris (5) precancerous and cancerous melanomas from the basal layer of epithelium and (6) benign and malignant chromatogenic melanoma derived from the mesodermal chromatoblasts (uvea, sacral and extracanal meibomian spots)

JOSEFA ZUCKERMAN M.D.

Roper Hall, M. J.: Research in Zurich. *Brü J Ophth.*, 1947 3: 23.

This article gives a summary of the work on the pathological changes in the aqueous humor and the blood-aqueous barrier carried on at Zurich. The specimen of aqueous was obtained with a special needle attached to a tuberculin syringe which enters the anterior chamber on a plane parallel to the iris and at a point about 3 mm from the limbus. A smear and culture were first taken from the conjunctival sac and a small scraping of corneal endothelium was removed from the point at which the puncture was to be made.

On the 0.2 c.c. of fluid obtained a study was carried out, including quantitative tests for albumin (Pandy reaction), cell count, cultures, and microscopic examination of the centrifuged material with various stains. The conjunctival and epithelial smears were examined and conjunctival cultures were correlated with the aqueous findings. More than 1,000 punctures were performed in the course of this research. The following findings were noted:

1. The normal aqueous contains from 0 to 1 cell per cubic millimeter.

2. The number of cells increases in cases of anterior uveitis and deep corneal ulcer usually to between 50 and 200 cells, but in a few cases up to 100,000 cells per cubic millimeter.

3. In acute inflammations the albumin is increased in proportion to the number of cells.

4. In chronic inflammations there is a dissociation between the albumin and the cell count as observed in the pathology of the cerebrospinal fluid.

5. Study of the morphology and origin of the cells indicates that the cells are derived from the blood and neighboring tissues.

6. The presence of microphages and macrophages in the specimens indicates the phagocytic and antitoxic function of the desquamated cells.

7. Of the 651 cases of endogenous and exogenous iridocyclitis, keratitis, and panophthalmitis, 19 per cent showed large reticuloendothelial cells which had phagocytized micro-organisms, thought to be staphylococci in most cases. Tubercle bacilli were found in only 1 case. Cultures are rarely positive (30 cases in the series).

8. The presence of micro-organisms in the anterior chamber in cases of iritis and keratitis may throw light on the etiology.

9. The absence of tubercle bacilli may throw some doubt on the importance of their role in the etiology of uveitis.

10. The type of organism found indicates the possibility of focal infections.

Studies on the blood-aqueous barrier were carried out with the intravenous injection of fluorescein and studies of the aqueous with an adapted slit lamp. Investigation of 200 normal eyes showed that there is a regular and gradual rise of fluorescein in the anterior chamber with the normal for children slightly higher than that for adults. After examining 1,000 cases by this method it was concluded:

1. In iridocyclitis there is an increase in permeability which corresponds to the severity of the disease.

2. In glaucoma there may be a normal or considerable increase in permeability perhaps indicating the etiology.

3. Ocular affections and trauma cause an increase in permeability, as well as some general diseases such as chronic nephritis, hepatitis, and especially diabetes.

4. Pilocarpine increases the permeability; atropine has no effect, and adrenalin decreases it.

Studies of the Tyndall effect suggest that it shows the permeability of the damaged blood-aqueous barrier to proteins and large molecules, while the fluorescein permeability shows the more minute change in the wall to small particles.

WILLIAM A. MAYER, M.D.

EAR

Mohs, F. E.: Chemosurgical Treatment of Cancer of the Ear; A Microscopically Controlled Method of Excision. *Surgery* 947: 605.

This article deals with the chemosurgical treatment of cancer of the ear and includes an analysis of the therapeutic results in a consecutive series of 107 lesions treated over a period of 9.5 years. Inasmuch as the behavior of squamous cell carcinoma is much different from that of basal cell carcinoma, the two histologic types are considered separately except in regard to the chemosurgical technique which is the same for both types.

The chemosurgical technique by which cancer of the ear may be excised under systematic microscopic control is described in detail.

The rates of cure in the series of patients with squamous cell carcinoma of the ear were: 80 per cent at 6 months or more, 74.3 per cent at 3 years or more, and 64.3 per cent at 5 years or more. The primary lesion was eradicated in 92 per cent of the patients.

The rates of cure in the series of 55 patients with basal cell carcinoma of the ear were: 93.3 per cent at 6 months or more, 87.1 per cent at 3 years or more, and 81 per cent at 5 years or more.

The reliability and the conservatism of the method are both due to the systematic microscopic control of excision afforded by the chemosurgical technique.

JOSE F. DELPUE, M.D.

NOSE AND SINUSES

Spar, Arthur A.; and Hallberg, Olav E.: Severe Epistaxis and Its Management; Report of 11 Cases in Which the External Carotid Artery was Ligated. *Ann Otol Rhinol.*, 1947 56 142

Since 1930 106 cases of epistaxis have been treated in hospitals connected with the Mayo Clinic. Of all the patients studied approximately 40 per cent had either hypertension or arteriosclerosis or both, which had been previously diagnosed. Forty per cent of all the patients were more than 60 years of age. Of those past 60 years 60 per cent had hypertension. In 29 cases presenting no obvious cause of hemorrhage or previous diagnosis of cardiovascular disease the epistaxis was classified as of undetermined cause. In nearly all of these however the patients were in the age group in which cardiovascular disease is common.

Most textbooks dismiss the anterior portion of the septum as being of only nuisance value, but half of the total number of these patients requiring hospitalization bled from this source. It is not surprising to those who routinely have to treat nosebleed that anterior septal bleeding can be so severe as to require hospital apparatus for its control. Three of 5 patients more than 60 years of age bled from this source.

Nearly a third of all patients bled from a point high and posterior in the nose, most of these from the sphenopalatine artery. Trauma incidental to packing the nose prior to hospitalization was found to be a considerable factor in the cases classified as bleeding from the turbinates or diffusely from the nasal membranes.

On admission to the hospital the patient is examined first for symptoms of shock and for active bleeding. If he is an adult he is given from $\frac{1}{4}$ to $\frac{1}{2}$ gr (from 0.01 to 0.016 gm.) of morphine by hypodermic injection. With close observation of the patient it is not difficult to distinguish between shock due to hemorrhage and the shocklike appearance of a patient who is nauseated from swallowing too much blood. If there is uncertainty as to the condition of the patient there need be no hesitancy in giving him a transfusion of blood. Liters of group O blood should be available for immediate use.

If the hemorrhage is controlled by packs inserted elsewhere prior to hospitalization the packs are left in place and the patient is watched thereafter for recurrence of bleeding.

If there is active bleeding, all packs are removed and the nose is quickly cleaned with a suction apparatus under direct vision to determine the source and severity of the bleeding. Cotton pledgets moistened in equal parts of a 1:1,000 solution of ephedrine chloride and a 10 per cent solution of cocaine are then used to shrink the nasal mucous membrane and provide local anesthesia for any necessary instrumentation. A length of 1 inch (2.5 cm.) gauze heavily covered with vaselin is probably the most useful agent available to the rhinol-

ogist for the control of nasal hemorrhage. Large spurting vessels do not respond to the chemical cautery and high posterior spurting vessels are inaccessible to the electrocoagulating point. A short strip of vaselin gauze, carefully and firmly packed over the bleeding point controlled hemorrhage in 80 of the cases of nosebleed.

There should be no hesitancy about inserting a postnasal pack if the anterior packing alone fails to stop the flow of blood. Chemoprophylaxis or antibiotics are routinely used in cases in which posterior packing is required.

Eleven patients failed to respond to conservative treatment and required ligation of the external carotid artery. Two of these developed minor wound infections and a third needed tracheotomy because of laryngeal edema from wound infection.

MOUTH

Oscar Ernesto Martín: The Mirault Blair Brown Operation on the Unilateral Harelip (The Flap Operation) (La operación de Mirault Blair Brown en el labio leporino unilateral). *Bol Soc cir Cordoba*, 1946, 7 436.

Types of unilateral harelip include (1) partial when the mucous membrane and border and adjacent skin only are involved (2) subtotal, when the cutaneous part of the lip is involved and (3) total, when the entire lip, nasal passages, and the gingival arch are affected.

Good surgical results must obtain the following: (1) symmetrical overhanging ala (2) symmetry of the nasal passage and columella (3) a satisfactory base for the nose (4) maintenance of normal curvature of the nose (5) a precise columella, (6) normal curvature of the upper lip and (7) even and properly proportioned mucosal and vermilion borders.

Steps of the subtotal and total harelip operations are given in detail with the cardinal points emphasized and illustrated.

The authors advocate surgical repair within the first 48 hours as the complications of the malformation are more easily avoided. Postoperative management must be assiduous. Nonabsorbable sutures are removed in from 4 to 6 days. Food is given from the first hours according to the patient's tolerance. Local anesthesia is preferred although some workers use ether.

STEPHEN A. ZIEGLER, M.D.

Seeley, R. C.: Maxillofacial Injuries. Reconstructive Surgery of the Dehiscent Parotid Duct and Dehiscent Peripheral Facial Nerve. *Am J Surg* 1947 73 551.

The purpose of this article is fourfold: to bring up to date the work done on parotid duct injuries; to review the literature to the date on the associated facial nerve injuries; to report a case and to present a logical surgical technique in the repair of maxillofacial injuries resulting in lacerations, obstructions, or dehiscences of the peripheral facial nerve and parotid duct.

One of the least commonly stressed injuries about the face is parotid duct injury particularly when the injury results in the dehiscence of the duct. Such an injury would necessarily be predicated upon a similar injury to the peripheral facial nerve. This article deals primarily with the secondary repair of the dehiscent parotid duct, dehiscent zygomatic branch of the facial nerve and repair of the buccal branch. The technique employed is one that can be utilized in either primary or secondary repairs.

In retrospect duct injuries have for the most part been considered quite separately with regard to methods of repair and these usually have been emphasized under two headings: (1) the immediate repair, and (2) repair of the duct with existing fistulas. With reference to the seventh nerve peripheral injuries, these too have been considered for the most part as separate entities notably by Furstenberg and Bunnell.

It is the contention of the author that, while many cases of separate injury of the duct and facial nerve exist in consequence of injuries of a type, it is more than likely that if parotid duct injury exists peripheral nerve injury is also present and vice versa. If a lacerating, penetrating or avulsion injury involves the parotid duct the buccal and zygomatic branches of the facial nerve will be involved.

The author believes that it is not necessary to convert external fistulas into internal fistulas as a method of repair and that it is practicable to explore, isolate, resect, and anastomose by primary suture as a method. That is better surgery in view of the nerve factors present. The author's case, after pathological resection and excision 43 days subsequent to the primary injury was successfully repaired despite the existence of a 30 mm. dehiscence of the duct proper and a 30 mm. dehiscence of the zygomatic branch of the facial nerve. An indwelling No. 30 alloy steel wire dowel, which can be carried out through the cheek with no residual evidence of a puncture wound externally is a dowel of new material which is unsurpassed in reducing capillary and surface tension factors.

The successful repair in the case presented should nullify the opinions of those who elect to extirpate the parotid gland or destroy it by radiation when obstruction or fistulas exist. JOHN F. DUNN, M.D.

Friedman, G. A.: Tracheotomy in Maxillofacial Surgery. *Surgery* 1947 755.

Severe maxillofacial wounds are often associated with other injuries and associated neck injury is especially important in this connection. Three questions must be answered: How much can be done? How shall it be done? How best can it be done?

The causes for acute respiratory obstruction such as hemorrhage into the air passages, edema of the aryepiglottic fold, and foreign bodies, are enumerated as well as the signs of acute respiratory obstruction.

In war surgery the primary concern is indication for tracheotomy when respiratory obstruction is not

yet present but diagnosis leads one to believe that it will ensue.

Among the causes are injuries to the base of the tongue, pharynx or larynx, with or without the presence of foreign bodies, large foreign bodies in the air passages which cannot be removed under direct vision, extensive soft tissue wounds of the face which may cause later destruction by the spread of inflammation to the mucous membranes of the air passages, extensive fractures of the mandible situated where the tongue cannot be held forward by mechanical means, extensive injury to the upper facial regions, especially when these close off the nasal passage completely, and severe fractures of several of the upper facial elements.

Postoperative inflammation may descend to involve the pharynx and subsequently the mucous membranes of the air passages. Injury to the recurrent laryngeal or the vagus nerve by direct trauma or by pressure from hemorrhage may cause paralysis of both cords if bilateral and extreme dyspnea may ensue.

Eleven cases are reported in detail with a description of the procedure accompanied by photographs.

Among other conclusions, the author states that horizontal incision of the skin is the natural and best one for tracheotomy. JOHN F. DUNN, M.D.

NECK

Lahay, Frank H., and Bartels, Elmer C.: The Use of Thiouracil, Thiobarbital, and Propylthiouracil in Patients with Hyperthyroidism. *Ann. Surg.* 1947 15 572.

The authors prepared 660 patients for surgery with thiouracil, thiobarbital or propylthiouracil during a 3 1/2 year period. In addition, 21 cases were treated over a long period of time without surgery. These compounds in adequate dose prevent synthesis of inorganic iodine into diiodotyrosine and thyroxine; the protein bound iodine decreases and the basal metabolism rate drops. In time myxedema may result. The microscopic appearance of the hyperplastic gland is not changed by these agents. The metabolic rate returns to normal with adequate dosage. The usual daily doses required are 600 mgm. of thiouracil, 50 mgm. of thiobarbital or 200 mgm. of propylthiouracil. (The original suggested dose, from 75 to 125 mgm. of propylthiouracil, has been found too small). With the above doses, the basal metabolism rate decreases 1.3 per day in patients having primary hyperthyroidism for less than 9 months, without iodine therapy. If iodine has been taken, or if hyperthyroidism has been present longer than a year irrespective of iodine, the daily decrease in the basal metabolism rate is 1.2. With toxic adenomas, especially if iodine has been given, the decrease may be as slow as 0.5 daily. The longest time required was 180 days. The incidence of complications was 23 per cent with thiobarbital, 9 per cent with thiouracil and 3 per cent with propylthiouracil. With propylthiouracil and with thiobarbital, only

cried and sobbed together. In succeeding months he became absorbed in the mysticism of the Bible, and, as "Ambassador of God," importuned the Pope for another crusade to free the Holy Sepulchre from the infidels. His sense of persecution grew stronger and stronger. If this was tertiary syphilis, it would indicate a more rapid progression than usual, for it was only about eight years since the first voyage on which the primary infection may be said to have occurred. However this would coincide with the rapid action of the spirochete in a member of a completely non-immunized group. Diagnosis is difficult, because of the chaotic mass of controversial material, but a detached historical spirit recognizes that, apart from the ophthalmia and the rheumatoid arthritis, syphilis would account for all of his symptoms, both in their nature and in the relative times of their occurrence. To explain them otherwise means considering a list of single and distinct pathological conditions, including relapsing fever, typhus or typhoid, rheumatic fever and valvular heart disease, followed by paranoia.

In the spring of 1502 Columbus began his fourth and last "farewell tour" of America. He wanted to find a strait through which he might sail west into Portuguese Asia. During most of the voyage he was too sick to leave his cabin. Cardiac dropsey added to the pains of arthritis made his life miserable enough without the hardships of exploration. Poor food and bad weather plagued his little fleet. Storms wrenched and strained his crazy worm-eaten ships as they wandered painfully among the keys and shoals he had named the Garden of the Queen. Mutiny blazed up in his crews. Shipwreck ran him aground on Jamaica, where the Nani-like conduct of his men started the first American Revolution. Only his ability to foretell an eclipse of the moon saved him and them from the revenge of the superstitious natives.

Arriving in Spain two years later he was so ill that he had to be carried ashore. Meanwhile friend Isabella had died of an intestinal tumor untreated because she was too modest to allow herself to be examined. Her scamp of a husband, Ferdinand, always hostile, was of no help to the

discoverer of Spain a new empire. Poor Columbus lived in misery attempting to follow the court on its interminable peregrinations. Unable to endure the jittery paces of the Andalusian horses, he was forced to hoist his swollen legs on mule-back or be carried in litters.

Valladolid lies in a cleft among barren, treeless mountains, a city drowning away the hours in its silent convents and dusty streets. There, heart sick and weary Columbus dragged himself after the court for the last time. There he lingered painfully until May of 1506 when his diseased heart valves finally played themselves out. He handed over into the hands of God his proud, courageous spirit,

A battered, wrecked old man,
Thrown on this savage shore, far far from home
Pent by the sea and dark rebellious brows
My terminus near
The clouds already closing in upon me,
The voyage balk'd, the course disputed, lost,
I yield my ships to Thee

Walt Whitman.

blood cell depression and fever have been observed with thiouracil there were white blood cell depression, fever, skin rash, swollen salivary glands, edema of the skin and death with agranulocytosis. The authors believe the use of thiobarbital should be abandoned.

In managing their patients, the authors require a white blood count every 10 to 14 days when the white cells decrease below 4,500 and when the granulocytes are below 45 per cent administration of the drug is stopped or continued very cautiously. Treatment of agranulocytosis requires the use of penicillin to prevent or cure infection, which is the cause of death. No benefit from pyridoxine or liver extract was seen in these patients. The penicillin is given intramuscularly and by throat spray.

Because of the increased vascularity and friability of the gland resulting from simple thiouracil, thiobarbital or propylthiouracil treatment with resulting difficulty in the surgical removal of the gland iodine is now given from the beginning of treatment and administration of the thiocompound is stopped 7 days before surgery. The 7 day period was chosen because agranulocytosis has been observed as late as 7 days after cessation of drug administration. This avoids agranulocytosis as a complication at the time of operation.

Iodine therapy is not used in patients with adenomatous goiters.

Surgery should be done with the patient in as nearly normal a state of metabolism as possible. If myxedema occurs before surgery there is danger of too great edema of the larynx and of too great sensitivity of the respiratory center to morphine. Tracheotomy had to be used once in such a situation.

There were 115 thyrocardiac patients and 26 diabetics among the 660 patients treated with thiocompounds. The new treatment has reduced the previous surgical mortality of 6.7 per cent among thyrocardiac patients to 0.87 per cent. The 1 fatality among the thyrocardiacs was the only death among the 660 cases, an over-all mortality of 0.15 per cent. A variety of complicating diseases were present, including recurring gallstone colic and thrombocytopenia. The thyroid condition was treated first then the complication.

An attempt was made to treat primary hyperthyroidism by medical means alone in 21 cases. Treatment varied from 2 to 30 months before remission occurred. After the thiouracil was stopped, 13 of the 21 cases presented a relapse. All of the 8 patients still in remission had mild cases. The authors believe that severe cases will always require surgery, but that there is still a basis for hope that mild cases may be cured or permanently controlled by medical means.

CLINTON H. THIELKE, M.D.

Penick, Rawley M., Jr.: The Use of Thyroid Extract with Thiouracil in the Preparation of the Thyrotoxic Patient. *Ann. Surg.* 1947 125 582.

The authors attempted to prevent hyperplasia of the thyroid with thiouracil as they thought there was

some danger of promoting cancerous change especially since invasive tumors in animals have been produced by simultaneous administration of thiouracil and a carcinogen. Since thiouracil hyperplasia is believed to be due to an increased secretion of pituitary thyrotropin which in turn is due to the decreased amount of thyroxin in the circulation the author gave 64 mgm. of desiccated thyroid along with 0.6 gm. of thiouracil to 6 patients with exophthalmic goiter. The preoperative course was similar to that in patients given thiouracil and iodine; there was satisfactory involution of the gland with accumulation of colloid. The vascularity in 3 of the cases was equal to that in thiouracil iodine treated patients and in 3 was thought to be slightly greater.

The author believes that desiccated thyroid is a satisfactory adjunct to thiouracil for preoperative preparation of thyrotoxic patients.

Morgana, M. E.: Toxic Effects of Thiourea, Thiouracil, Methyl Thiouracil and Aminothiazole in Thyrotoxicosis. *Lancet* Lond 1947 1 519.

A series of 92 patients with thyrotoxicosis were treated with thiourea (7), thiouracil (49), methyl thiouracil (3) and aminothiazole (13) to determine the toxic effects of these drugs during the initial phases of treatment.

A table is presented in which the effect of these 4 thiourea drugs on the granular cells during the first 3 weeks of treatment is shown. The greatest decrease occurred at the end of the first week and in the methyl thiouracil series. With aminothiazole the granular cell count was halved during the first 3 weeks and in 38 per cent of the cases the absolute granular cell count was lowered more than 1,000 per cubic millimeter from initial levels.

A comprehensive incidence of complications is shown in a table for these drugs and the dosage used during the first 2 months of treatment. Methyl thiouracil and thiouracil produce a decrease of the white cells and in some cases leucopenia, but the incidence of other dosage effects is very low. From the author's point of view thiourea and aminothiazole have many toxic effects and their clinical use is no longer justifiable.

RICHARD J. BENNETT JR., M.D.

Williams, R. H., Asper, S. P., Jr., Rogers W. F. Jr., Myers, J. D. and Lloyd, C. W.: Persistence of Remissions of Thyrotoxicosis after Cessation of Thiouracil Therapy. *England J. M.* 1947 236 737

Of 111 thyrotoxic patients who were treated with thiouracil and had a cessation of therapy 51 are in remissions that have lasted for 3 to 31 months. Forty four patients have been free of thyrotoxicosis for more than a year after cessation of therapy and 33 have remained well for more than 18 months. Of all the patients who remained well without treatment for more than a year only 1 had a relapse. Following the cessation of treatment with thiouracil most of

the patients who had a relapse had it within a few months, 70 per cent had it within 3 months, and 85 per cent within 5 months.

Factors that have tended to favor persistent remissions were as follows: female sex, small goiter and a mild degree of thyrotoxicosis. The age of the patient, the duration of the disease, and the nodularity of the thyroid gland were not found to exert a significant influence, but these factors may prove important when larger series of cases are analyzed.

The good effects obtained with thiouracil encourage the frequent use of its less toxic derivatives, 6-propylthiouracil in the treatment of thyrotoxicosis. This therapy, radioactive iodine, or a combination of the two, appears to offer the most satisfactory method of treating the majority of patients with thyrotoxicosis, but further experience may reveal complications from these types of treatment that are of greater magnitude than are anticipated at present. Therefore, patients treated by these newer methods must be followed carefully.

Arendt, J., and Wolf, A.: The Vallecular Sign; Its Diagnosis and Its Clinical Significance. *Am. J. Roentg.* 1947 57 435.

The "vallecular sign" consists of the retention of barium mixture during the swallowing act in the pockets of the valleculae and in the pyriform sinuses. The findings have been such that they might be taken as a differential diagnostic sign pointing to organic disease. This sign has been observed in bulbar paralysis, myasthenia gravis, carcinoma of the cardiac end of the stomach, carcinoma of the hypopharynx, suspected paramedastinal lung tumor perforating carcinoma of the esophagus, and a case of abnormal origin of the right subclavian artery with clinical symptoms of dysphagia lusoria.

Eight cases are presented in detail along with 17 figures. The presence of the "vallecular sign" points to an organic lesion and not to a functional type of dysphagia. *RICHARD J. BENNETT, JR., M.D.*

Leahy, Frank H.: Parathyroid Tumors. *Surg. Clin. N. America*, 1947 27 477.

There are four types of parathyroid tumors: (1) discrete nonhyperfunctioning adenomas of the parathyroid; (2) cystic degeneration within such an adenoma producing a cyst of the parathyroid; (3) hyperfunctioning parathyroid adenoma; and (4) localized malignancy in the neck arising from a parathyroid gland.

In patients with clinical signs of hyperparathyroidism on whom an operative procedure must be performed to discover the hyperfunctioning parathyroid adenoma, it is of the utmost importance to be familiar with the appearance and probable location of the normal glands. In most cases 4 parathyroid glands are present, 2 at the upper and 2 at the lower pole. The glands at the upper pole are usually situated at the point where the upper lobes of the thyroid rest against the larynx, in relation particularly to the horn of the thyroid cartilage. To demonstrate these

glands it is usually necessary to ligate the superior thyroid artery and roll the superior pole of the thyroid downward and inward. The inferior parathyroids are more difficult to demonstrate; their frequent location within the branches of the inferior thyroid artery and vein makes the necessary blood vessel dissection difficult. Also at this location fat as well as lymphoid and thymic tissue can easily be confused with parathyroid tissue.

Anomalous positions of the glands are quite common. Parathyroid glands have been found on the anterior surface of the thyroid within the substance of the thyroid gland, beneath the clavicle and in the mediastinum. The normal parathyroids vary in size from structures not much larger than the head of a match up to those the size of a pea or bean. They usually have a distinctive light mahogany yellowish brown color. Another distinctive feature of the parathyroid glands is their flat disklike shape. In the presence of a hyperfunctioning adenoma the remaining normal glands may be quite inactive; such glands are filled with fat, are pale in color, and do not look like normal parathyroids. In the event that the hyperfunctioning adenoma is not readily found, it is of great value (if possible) to identify the 3 normal glands in order to have definite indications as to the location of the adenoma. It must not be forgotten that on occasion the hyperfunctioning adenoma is within the substance of the thyroid gland.

The diagnosis of hyperparathyroidism, when it is present in a well developed state, is not difficult; the presence of varying degrees of decalcification of the bony skeleton, and the typical blood chemistry changes of high calcium, low phosphorus, and high phosphatase blood values are diagnostic. However, the diagnosis of hyperparathyroidism should not be delayed until pronounced decalcification has taken place. Any evidence of bone rarefaction, spontaneous fracture, and kidney stones should arouse suspicion of this disease. Calcium excretion in the urine can be simply estimated by means of the Sulkowitch test: 2 c.c. of acid urine are mixed with an equal amount of Sulkowitch reagent and the turbidity read qualitatively.

Attention is called to the danger of tetany following the surgical removal of a hyperfunctioning adenoma. Also while recalcification is progressing during the postoperative period orthopedic support in proper positions may be necessary so that the recalcification does not exaggerate the positions of deformity. *F. J. LEAHY, JR., M.D.*

Goldberg, H. M.: Carotid Body Tumors. *Br. J. Surg.* 1947 34 793.

Two detailed case reports of rare carotid body tumors with survival and without complications after ligation of the common carotid artery are presented. A review of the subject is discussed.

The carotid body is inconstant in man and when present is situated behind the common carotid artery at its bifurcation.

Extirpation or absence of the carotid bodies has no adverse effect.

Tumors constitute the only pathological lesion of the carotid body. About 265 cases have so far been reported. They are slow growing tumors, usually benign at first, but they may become malignant later.

The majority of tumors arise from the epithelial type of cell. Two patterns, the alveolar and the peritheliomatous, have been described.

Tumors of the carotid body occur with equal frequency in both sexes. Both sides are equally affected. The average age of the patients is 43 years.

The most frequent history is that of a painless unilateral slow growing tumor in the neck. Rarely the tumor is sensitive to touch, but it is never painful. Other symptoms are due to compression or invasion of the surrounding structures. These are not frequently encountered. Hoarseness, dyspnea, dysphagia, cough and tinnitus may be due to compression of the vagus. Horner's syndrome, due to pressure on the cervical sympathetic, and carache due to involvement of the cervical plexus have been reported. Fainting attacks are due to the coexistence of a sensitive carotid sinus.

Overactivity of the carotid sinus reflex has been associated with a carotid body tumor in 5 of 260 cases found in the literature and in 1 case of the author's. The nerve supply of the sinus is similar to that of the carotid body being derived chiefly from the glossopharyngeal nerve by way of the carotid sinus nerve of Hering and probably also from the vagus, hypoglossal and the sympathetic nerve. A tumor of the carotid body may therefore, occasionally produce an overactive sinus by 2 mechanisms, either by direct pressure or by way of a reflex arc. Other lesions in the neighborhood of the bifurcation of the common carotid, such as cervical lymphadenopathies (chiefly tuberculous) are very occasionally associated with a hypersensitive sinus.

Carotid sinus syncope can be precipitated in subjects with a sensitive sinus by a sudden turning of the head wearing tight collars, or by pressure over the sinus. It is characterized by pallor, hyperpnea, muscular twitching and dizziness followed by unconsciousness. Flushing of the face occurs on recovery. Two types of carotid sinus syncope are recognized according to which of the 2 efferent pathways, the vagus or the vasomotor depressor nerves, predominates.

In the cardioinhibitory type in which vagal cardiac inhibition is the predominant factor a marked fall in the blood pressure is associated with complete asystole or ventricular standstill. The electrocardiogram during the attack shows no alteration of potential or only a succession of P waves. This reaction can often be prevented by atropine.

In the vasodepressor type vasodilatation causes a fall in the blood pressure and the consequent cerebral anemia results in unconsciousness. The cardiac rate does not slow markedly and vagal stimulation of the heart produces at the most nodal escape so that the electrocardiogram shows either no alteration from normal or absent P waves.

This type may often be relieved by sympathomimetic drugs such as ephedrine or benzedrine.

The electroencephalogram shows moderate to high voltage slow (delta) waves during unconsciousness. This is an unspecific response and can be seen in syncope from various causes such as venepuncture and distension of the colon and rectum.

A third type has been described, in which syncope is unassociated with any significant alteration in the blood pressure or cardiac rate. This has been called the cerebral type but its existence is doubtful.

The tumors are ovoid or round in shape situated at the bifurcation of the common carotid artery and lying partly under the sternomastoid (elevating the anterior border of that muscle) and partly in front of it. The surface is smooth or finely lobulated. The consistency is firm resembling the texture of a fibrotic tuberculous gland. Lying within the carotid sheath firmly attached to the artery they can be moved from side to side but not vertically. On account of their vascularity they can be temporarily reduced by pressure. Compression of the common carotid artery also temporarily reduces their size. Transmitted pulsation can always be elicited. A few tumors present a bruit and thrill. A sensitive carotid sinus, if present on the same side as the tumor will give rise to the typical attacks on pressure on the tumor for about 30 seconds. The pharyngeal wall is occasionally displaced by the tumor and physical signs due to pressure on the surrounding nerves are found occasionally.

The correct preoperative diagnosis has only been made in 25 of 180 tumors. The most common erroneous diagnoses are tuberculous glands, branchial cyst, aneurysm, and lateral aberrant thyroid tumor. Secondary malignant glands, branchial carcinoma, neurofibroma, lymphadenoma, and lymphosarcoma must also be considered. A punch biopsy has been suggested but has been thought dangerous by most workers on account of the vascularity of the carotid body tumor. Even biopsy can be misleading.

The criteria on which to base the diagnosis of carotid body tumors are:

1. A history extending over several years of a slow growing painless tumor in the neck.
2. A firm oval tumor in the region of the bifurcation of the common carotid.
3. Free lateral but very limited or no vertical mobility.
4. Decrease in size on compression of the common carotid artery.
5. Transmitted but no expansile pulsation.

The prognosis depends on whether the common carotid has to be ligated and whether invasion has occurred before operation. The operative mortality is 15 per cent without ligation and 30 per cent when the artery has been tied.

The age of the patient and the duration of the condition are not a guide as to whether malignancy has supervened. More rapid growth and horizontal fixation may be taken as an indication of malignancy.

nancy. Usually it is only at operation when difficulty is encountered in shelling out the tumor that the invasive character is manifest. Nor is age an infallible indication whether hemiplegia may occur after division of the common carotid. The youngest patient with a carotid body tumor in whom ligation of the common carotid resulted in hemiplegia was 26 years old.

Radiotherapy does not appear to have any effect on carotid body tumors. The ideal treatment is total removal of the tumor without carotid ligation.

Hemiplegia may come on immediately after operation when it is due to deficient collateral circulation of the cerebral hemisphere, or it may be delayed for 24 hours or longer when it may be due to occlusion of the middle cerebral artery by ascending thromboses. The hemiplegia may be permanent, but often it is only transitory and leaves very little final disability.

An electroencephalogram after compression of the common carotid for from 30 to 60 minutes is the best indication of the competence of the collateral circulation, although it does not exclude the danger of delayed hemiplegia. If the electroencephalographic studies show a deficient collateral circulation and during the course of the operation it becomes obvious that the tumor is inseparable from the vessels, it may be wiser to abandon the operation and to rely on what little help x rays can give.

In order to lessen the incidence of hemiplegia manual carotid compression for periods up to 30 minutes for 2 to 3 weeks before operation has been advised. The efficiency of the procedure has not yet been proved. This could be done by a series of electroencephalogram studies. Mechanical devices to close the carotid gradually have been used; a clamp which can be tightened daily; metal bands and others.

A general anesthetic has been used in most cases as the operation tends to be a long one. The incision should be generous and should run either along the skin creases or along the anterior border of the sternomastoid muscle. The platysma is divided as well and the flaps raised to beyond the borders of the tumor. The deep fascia is incised along the anterior border of the sternomastoid and the muscle retracted posteriorly. The carotid sheath is now opened below the tumor; the common carotid isolated and a ligature put around it; the ligature is not tied. This is a safeguard in case the artery is torn during the dissection. The internal jugular vein is either stretched across the tumor or pushed backward and is usually divided. The vagus and sympathetic lie behind the tumor in the carotid sheath and must be carefully preserved. The superior laryngeal nerve of the vagus may be divided if it gets in the way. The hypoglossal nerve should be kept out of harm's way as it runs forward medial to the upper pole of the tumor. The tumor is freed from the surrounding structures on all sides. It can be rotated from side to side to put all adherent

structures on the stretch. An attempt should be made to dissect it off the arteries. If the vessels are not completely encircled this should be done by sharp dissection, but if they are completely surrounded it is recommended that an artery forceps be inserted along the vessel from below and dividing the overlying tissues between clamps, much as one would separate the thyroid isthmus from the trachea. It is during this procedure that the vessel is most likely to be torn. If the vessel has to be tied it should be transected at the same time. The tumor can now be pulled upward to expose the vagus in its bed and dissection proceeds from below upward. The internal and external carotid arteries are then tied and transected and the tumor is removed. The skin and platysma are sutured; a small drain being left at the lower end of the wound.

Following ligation of the common carotid the patient should be kept in the Trendelenburg position for 10 days and not allowed up for another 2 to 3 weeks. This minimizes the danger of cerebral anemia, which is the most common postoperative complication, giving rise to hemiplegia, aphasia, facial palsy and unconsciousness. Deviation of the tongue would follow hypoglossal injury and vocal cord paralysis would follow damage to the recurrent laryngeal nerve.

JOHN E. KARANTZ, M.D.

Marshall, Samuel F., and Miles, George O.: Tumors of the Submaxillary and Parotid Gland Areas. *Surg. Clin. N. America*, 1947 37 301.

This report is based on a study of 150 tumors of the parotid and submaxillary region. Similar tumors may also arise from the oral cavity, nasopharynx, accessory nasal sinuses, lacrimal gland and middle ear. When present in these locations the tumors arise from the mucous glands of the area. There were 24 cases of cancer of the salivary gland in this series, 4 of which were of lymphoblastic origin. Parotitis is the most common nonneoplastic swelling confused with parotid neoplasia. A small tumor of only a few weeks' duration should be treated with suspicion. Parotitis is usually tender to palpation, a most important differential diagnostic point but if the inflammatory process has become chronic the tenderness may disappear. Angiomas, sebaceous cysts, branchial cleft cysts, and hyperplastic adenitis must also be considered in the differential diagnosis.

In these cases 99 of the patients were females and 5 were males. The average time elapsing before operation was 10.6 years. Frequently with malignant growths a history of rapid enlargement was obtained. Only 2 patients with parotid carcinoma noted paralysis before they discovered a tumor. On physical examination, fixation of the tumor is the most presumptive physical sign of carcinoma. The author does not agree with the statement that small tumors are more likely to recur after operation than large ones. The two major considerations in the operative procedure are to remove a liberal margin of normal salivary gland to avoid recurrence, and to avoid

injury of the facial nerve. To accomplish this the authors isolate and identify the nerve in all cases except those with the most superficially located tumors. Of 13 patients with benign parotid or submaxillary tumors who had no previous surgery, 2 (15%) had a subsequent recurrence. Of 10 with parotid or submaxillary carcinoma, 9 (90%) had a subsequent recurrence. Epidermoid cancer and adenocarcinoma in general give a less favorable prognosis than malignant mixed tumors.

When a decision has to be made during operation between sacrificing the main trunk of the nerve and accomplishing an unsatisfactory excision the opinion of a pathologist as to the type of tumor may indicate removal of the nerve. Otherwise the authors make every effort not to enter the tumor bed. There is a great difference in morbidity in cutting the lower and upper divisions of the main nerve trunk. The authors do not hesitate to cut the mandibular branch of the facial nerve for benign disease if necessary nor do they hesitate to sacrifice any part of the nerve in cases of carcinoma if the nerve definitely traverses the tumor.

The authors strongly recommend isolation of the main trunk of the nerve in all but the most superficial benign parotid tumors. They isolate the nerve as it exits from the stylomastoid foramen and by careful dissection follow it forward. Before the actual isolation of the nerve is accomplished the external maxillary artery is identified and ligated which markedly reduces bleeding in the operative area. The nerve itself leaves the stylomastoid foramen 1 or 2 cm. medial to the lateral surface of the mastoid process and 1 cm. superior to its tip.

Ruzicka, Edwin R., and Eversole, Urban H.: The Management of Anesthesia for Surgery of the Neck. *Surg Clin N America*, 1947 27 517

Of fundamental importance in the administration of anesthesia, particularly in cases of neck surgery, is the maintenance of a clear airway. Endotracheal tubes are often indicated. The author advises against the routine use of blind intubation by the nasotracheal route. Profuse nasal hemorrhage may be a serious complication. Fluids should be administered through a leg vein.

General anesthesia is recommended in all cases of thyroid surgery. Cyclopropane has the serious disadvantage of increasing the irritability of the heart muscle and should probably not be used on thyrotoxic patients. The endotracheal tube should be used when there is deviation or compression of the trachea, cancer of the thyroid, intrathoracic extension of the tumor, paralysis of either or both vocal cords, and for all secondary operations. If there is marked encroachment on the airways by the thyroid tumor

or if preoperative stridor is present the endotracheal tube should be placed in position under topical anesthesia before a general anesthetic is administered.

When surgery is being performed for esophageal diverticulum no oral preoperative medication should be given because of the possibility that the medication may enter the diverticulum and thus exert no effect. An endotracheal tube with an inflatable cuff should always be employed to prevent aspiration. Laryngoscopy, bronchoscopy and esophagoscopy may be performed under sodium pentothal and curare anesthesia.

Laryngectomy presents a problem in the maintenance of an airway. If a tracheotomy has been previously established the tracheotomy tube can be removed under pentothal anesthesia and a metal endotracheal tube with an inflatable rubber cuff may then be placed in the trachea. An excellent airway is thereby maintained. If a tracheotomy has not been done previously the orotracheal tube is used in the usual manner until the larynx is excised and the tube is then inserted into the tracheotomy opening. Patients with bilateral vocal cord paralysis often need emergency endotracheal intubation and this can best be done under topical anesthesia.

Brunschwig, Alexander; and Camp, Edward: One-Stage Resection of Total Cervical Esophagus, Larynx, Base of Tongue, Hypopharynx, Cervical Trachea, and Bilateral Cervical Lymph Node Chains for Carcinoma Primary in the Cervical Esophagus; Reconstruction of the Cervical Esophagus. *Laryngoscope* 1947 57 305

The authors relate the case history of a woman 33 years of age who had a squamous cell carcinoma arising on the anterior wall of the cervical esophagus immediately adjacent to the larynx. To insure adequate removal of the tumor it was necessary to remove the larynx, cervical trachea, base of the tongue, the hypopharynx, and the cervical esophagus together with the cervical chain of lymph nodes on each side.

Reconstruction of the esophagus was begun at the initial operation by creating half a cutaneous tube or gutter from the oropharynx to the transected esophagus by use of a skin flap from the neck. At a second operation 10 weeks later the other half of the cutaneous tube was fashioned by raising a skin flap again from the side of the neck. Dermatomic grafts and pinch grafts were used to epithelize the raw surfaces.

Diagrams and photographs are used to illustrate the technique and result.

The authors believe that the case illustrates the feasibility of radical surgical attack upon cervical esophageal cancer.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Davis, Loyal; and Perrat, George: Cerebral Thromboangiitis Obliterans. *Brit. J. Surg.* 1947 34 307

Eleven cases of cerebral thromboangiitis obliterans are presented with signs and symptoms similar to those produced by a slowly growing intracranial tumor. Only 3 of the patients had evidence of peripheral circulatory disturbances. In 9 of the 11 cases with a similar clinical picture an osteoplastic craniotomy was performed. The gross and microscopic changes in the cerebral vessels are described and the changes are illustrated in several photographs made at the time of operation. The anatomical diagnosis is made by the presence of the characteristic small, white, wormlike obliterated vessels, the granular atrophy of the cortex, and the presence of thrombi associated with proliferation of the endothelial cells of the intimal and subintimal layers of the vessels.

The clinical diagnosis is more difficult. Cerebral thromboangiitis obliterans occurs most commonly in people between the ages of 30 and 50. Most symptoms are transient in the beginning, come in attacks, and recede completely. The history is usually of long duration and is characterized by unilateral sensory disturbances followed by weakness and transitory paralysis. Speech disturbances and visual field defects were also common.

Air studies were performed in 6 cases and the pre-dominant findings were cerebral atrophy with enlargement of the ventricular system and subarachnoid spaces. Arteriography was not performed in any of the cases.

An excellent bibliography and review of the literature is given. The purely cerebral form was first described by Foerster and Guttman in 1933. It is frequently diagnosed as lues, juvenile arteriosclerosis, hypertension, atypical multiple sclerosis, or an intracranial tumor. The condition is not as rare as might be expected and may very well be responsible for many organic cerebral changes which are not clearly diagnosed and which masquerade under the name of other diseases. Howard H. Laxner, M.D.

McNickle, H. F.: The Surgical Treatment of Hydrocephalus. *Brit. J. Surg.* 1947 34 303.

The author describes a method of performing third ventriculostomy for the surgical relief of hydrocephalus. Briefly the method is to puncture the floor of the third ventricle by means of a hollow needle passed from above into a lateral ventricle, directed through the foramen of Monro into the third ventricle by touch or by telescope and advanced to its destination under the x-ray screen.

Four cases of noncommunicating hydrocephalus and 3 cases of communicating hydrocephalus were treated and the results presented. The author be-

lieves that the division of hydrocephalus into communicating and noncommunicating types is an arbitrary one and has been overemphasized. He also states that cauterization of the choroid plexus seems to be wrong in principle. Floating debris after the operation must sometimes aggravate the hydrocephalus.

Included also is a discussion of the cause of hydrocephalus. The rationale of third ventriculostomy is given, and suggestions are made for the prevention and treatment of the type of hydrocephalus associated with lumbar myelomeningocele.

HOWARD H. LAXNER, M.D.

SPINAL CORD AND ITS COVERINGS

Barr, Joseph S.: Ruptured Intervertebral Disc and Sciatic Pain. *J. Bone Surg.* 1947 29: 499.

In 1934, Mixter and Barr drew attention to the syndrome of the protruding intervertebral disc and since that time the subject has been of considerable interest to neurosurgeons and orthopedic surgeons throughout the world. It is fitting, therefore, that one of the co-authors of that original paper should now summarize his views on the subject of the development of the syndrome and the various aspects of it which are of interest to all those who have to deal with this condition.

In the present article the author reviews the end-results obtained in patients treated for ruptured disc in the years 1939 to 1943, inclusive. The study comprises 134 cases—103 with spinal fusion and 31 with out spinal fusion. Some of the patients were sent a questionnaire to be filled out; others reported for re-examination and re-evaluation. The questionnaire goes into sufficient detail to bring out the points that are of interest in the end-result. Of particular interest is the comparison of improvement in patients with, and in patients without spinal fusion. The tables are set up in such a way as to show the differences between these two types of treatment by placing the statistical studies side by side. The results of the questionnaire show a slight but definite superiority of the result obtained with fusion over the result obtained without fusion when all types of complaints and disabilities are considered. There was one death from massive pulmonary embolism 17 days following the operation of spinal fusion.

In a series of 24 compensation cases, 60 per cent of the patients had absolutely no complaint and 71 per cent were back at full duty. It is pointed out that some of the poor results in compensation cases are due to improper treatment and neglect, mental and physical deterioration, poor operative technique, and unnecessary weakening of the architecture of the spine; also, there are conditions still diagnosed as ruptured disc in spite of negative exploration. Many compensation cases are those of laborers whose work

REVIEWS OF NEW BOOKS

BECAUSE the author of *Postgraduate Obstetrics*¹ has had extensive experience as a teacher of postgraduate courses, this book is distinctly authoritative. He has attempted to discuss only subjects which should be of interest to the average family doctor based on the statistical frequency of obstetric complications.

The chapter dealing with the toxemias of pregnancy is admirably presented and it emphasizes the conservative attitude of nearly all obstetricians as regards the treatment of eclampsia. However one does not agree with the author's statement that "it is justifiable to state didactically that *eclampsia represents a contraindication to cesarean section* (author's italics). In rare instances a cesarean section under direct infiltration anesthesia is justifiable in the presence of eclampsia.

In the section on the acute infectious diseases such unusual diseases in pregnancy as small pox, scarlet fever, measles and malaria are discussed. German measles, which is important because of its harmful effects on the fetus *in utero* when it occurs during the first three months of gestation is omitted. One has less faith than Mengert in cystography as an aid in the diagnosis of placenta previa. Many believe that the Braxton Hicks version which is described as one form of treatment of placenta previa should be given up entirely because it is a dangerous procedure even for specialists. On the other hand, contrary to the author one believes that a cesarean section is indicated in all cases of total placenta previa, even if the baby is not viable or is dead, so as to prevent maternal death or injury.

One agrees that premature artificial rupture of the membranes represents the safest method of induction of labor provided the proper conditions are present but it is doubtful that when pituitary extract is used for induction as much as 6 minims can be used as one dose with impunity. Rupture of the uterus has followed even 1 minim doses given for induction of labor. In the section dealing with uterine inertia, Mengert properly warns that the use of more than 2 minim doses imposes intolerable maternal and fetal risks. In the discussion on postpartum hemorrhage one believes two recommendations should be omitted namely the use of the Credé maneuver even if bleeding is not checked by oxytocic drugs and the use of intrauterine douches. There may be a question as to whether it is proper in a book on postgraduate obstetrics to include a detailed chapter on sterility including the matters of adoption of a baby and artificial insemination. Minor criticisms are the frequent use of the word "pituitrin," a trade name instead of the term "posterior pituitary extract" and the secondary position (in parentheses) assigned to the metric system. The use of the metric system in deal-

ing with medical subjects conforms with practically all foreign medical literature and many representative American journals.

In spite of suggested differences of opinion this book is a valuable contribution. It covers all the obstetric subjects with which general practitioners must be familiar; it is well written by one of the foremost obstetricians; it contains sound practical advice and it has numerous instructive illustrations most of which are beautiful drawings by Ruth Maxwell Sanders. The book has been printed on paper of good quality, the type is clear and the illustrations have been well reproduced.

J. P. GREENHILL

THE monograph *Penicillin in Neurology*² devotes approximately one-half of its text to basic studies describing the dispersion and absorption of penicillin when injected intrathecally and to the effect of this drug upon normal nervous tissue. Four of ten chapters are concerned with penicillin therapy in meningitis, in infections of the skull and brain, in diseases of the spinal cord and its coverings, and in syphilis of the central nervous system. A final chapter recounts briefly the relation of antibiotics other than penicillin to the normal and diseased central nervous system. Selected references 311 in total number are appended to each chapter. The authors may be considered as authorities since they were among the first, if not the first, to report certain noxious influences of penicillin upon the intact and infected brain. These clinical observations have been followed by a series of lengthy and critical experimental investigations.

The textual material and the well chosen illustrations and charts, largely a summation of the authors' own experiences, combine to form a scholarly description of the biophysiology of penicillin. The discussions of penicillin therapy suffer only from the usual need of terminating a modern monograph at some definite publication date and from the obvious fact that antibiotic therapy is a matter of daily accruing data. This deficiency is most noticeable in the chapter devoted to streptomycin, streptothricin, actinomycin, and clavacin.

The wisdom of including a chapter upon the value of penicillin in syphilis is open to the contention that this might be evaluated more clearly by contrast to other methods of therapy detailed in a specialized text upon syphilis. Neurologists and neurosurgeons should be very content with this monograph however and make this edition and future editions mandatory reading for their students.

involves considerable back strain. It is pointed out that one cannot expect to return these patients to work for at least 6 months.

The author reports his experiences at the United States Naval Hospital, Bethesda, Maryland. Prior to his arrival the neurosurgeons were removing discs without spinal fusion but they were glad to co-operate with him in performing fusion in a great many if not most of the cases observed after his arrival at that institution. The enlisted personnel however, following the operation of removal of discs and spinal fusions were not considered suitable for full duty as this involved twisting and lifting.

The technique of fusion employed by the author is that previously described by Bosworth and consists essentially of a clothes-pin graft taken from the ilium. Myelography was used routinely in these cases with removal of the pantopaque. A conservative preliminary attitude is recommended for at least a period of 6 weeks as an operation of this magnitude is not considered to be without risk. The author believes that the best trend of treatment is towards removal of the disc and fusion of the spine. Views are expressed on related details associated with the diagnosis and treatment of the ruptured intervertebral disc with sciatic pain.

ADRIEN VEX BROUHAEN, M.D.

Lenhard, Raymond E.: End Result Study of the Intervertebral Disc. *J Bone Surg* 1947 29 435

The author presents a condensed four page statistical study of the end results obtained by Walter Dandy in the treatment of the intervertebral disc. Eight hundred and forty three patients were operated upon during the period from 1917 to 1944 inclusive, and in March 1945 questionnaires were sent out. Five hundred and thirteen or 60 per cent of the patients, returned the questionnaire and 147 patients returned for examination. These formed the basis of the study.

There were three phases of development of the treatment carried out in these cases. Before January 1917 the loose fragments were removed. During the period between January 1917 and January 1918 a curettage or removal of the entire disc was carried out. After June 1918 multiple discs were recognized and removed completely. The third procedure produced the best results.

Examination of the 147 patients revealed good results in 67.5 per cent of the patients. Improvement in 17 per cent, and no improvement in 15.5 per cent of the patients. Of the 513 patients replying to the questionnaire (not examined) good results were obtained in 59.5 per cent, improvement in 22.0 per cent and no improvement in 17.6 per cent. A few of the patients were entirely relieved of symptoms and were able to perform their normal duties without complaint. In none of these patients was fusion accomplished according to any orthopedic standard. Among the 147 patients who returned for examination, 20 had had multiple operations, 16 had had 2 operations, 3 had had 3 operations and 2 patients had had 4 operations.

Pantopaque studies were not used routinely as in 90 per cent of the patients the lesion was said to have occurred at the fourth and fifth lumbar vertebrae. There was no distinct relationship between the narrowed space and the faulty disc. The author points out that prior to 1917 Dandy doubted the frequency of occurrence of ruptured disc, but after he had seen many cases he became convinced that all low back pain with or without sciatic pain was caused by injury or abnormality of the intervertebral discs.

ADRIEN VEX BROUHAEN, M.D.

Livingstone, R. G., and Leach, J. E. Intrathecal Penicillin in Bacterial Meningitis. *Surgery* 1947 21 683

The variable reports regarding the efficacy of penicillin by various routes of administration warrants any additional information that will be of benefit. The present report, from the Memorial Hospital, New York, concerns 3 patients with meningitis, in whom the intrathecal administration of large doses of penicillin was believed to be of unequivocal benefit.

In both cases the meningitis was due to direct invasion of the subarachnoid spaces following operative procedure about the nasal cavity and ethmoid and sphenoid sinuses respectively. At the onset, therapy consisted of treatment with penicillin intramuscularly and with sulfonamides orally in the doses usually recommended.

In the first case the infection (*Streptococcus viridans*) was not controlled over a period of 27 days despite the administration of 8,640,000 units of penicillin. At that time 100,000 units of sodium penicillin dissolved in 5 c.c. of spinal fluid were injected intrathecally daily. On the fourth day the patient had two generalized convulsive seizures on the fifth day she was found to be disoriented and drowsy. Only 10,000 units were given intrathecally for another 3 days and all medication was then discontinued since the laboratory tests and temperature indicated that the patient had recovered. Although the authors believe that the convulsions and mental aberrative episodes were not due to penicillin this point is easily doubted. However the undoubted control of the infection is of the greatest importance.

In the second case, the patient was treated with 50,000 units of sodium penicillin in 5 c.c. of spinal fluid injected very slowly intrathecally. This was started at the beginning of the meningitis although the patient had been receiving penicillin and the sulfonamides prophylactically for 3 days. Cultures revealed a pure growth of *Streptococcus hemolyticus* (group A). Subsequent studies revealed the organism to be relatively resistant to penicillin. No untoward neurotoxic signs were noted.

Despite the known potential dangers of penicillin intrathecally the use of large doses of penicillin in the absence of lumbar block is recommended in fulminating and resistant cases of meningitis.

SYMPATHETIC NERVES

Guttmann L., Riches, E. W., Whitteridge D. Johnson P. H. A., and Others: Discussion on the Treatment and Prognosis of Traumatic Paraplegia. *Proc. R. Soc. M. Lond.* 937 4 319.

CUTTMAN. The studies in this article were made upon 177 casualties who were patients in the Spinal Injuries Center, Ministry of Pensions Hospital, Stoke Mandeville since February 1944. Of this group 108 patients had suffered gunshot injuries while 69 had fractures of the spine. Emphasis was placed on the care of the bladder with the use of the intermittent or constant indwelling catheter and modified tidal drainage. Suprapubic cyst tomy was deemed preferable for cases with narrow urethras, urethral strictures, or presenting other focal urethral injuries. The development of the automatic reflex activity of the bladder and voluntary micturition by pressure was encouraged. Prevention of stone formation was accomplished by shortening the interval of recumbency and by restoring the best possible fitness of the patient. Stress was placed on the importance of recognition of autonomic phenomena above the site of a complete cervical or thoracic cord lesion caused by abnormal distention of a viscus without pain below the site of the lesion. Prevention of contractures and atrophy were carried out by adequate physiotherapy. Control of spasms was accomplished in selected cases by the intramedullary injection of 1 to 2 c.c. of 80 per cent alcohol into the thoracolumbar junction. For generalized rehabilitation of paraplegics a center has been set up near Macclesfield to provide aid in social and industrial readjustment.

RICHES. In care of the bladder drainage is essential but it need not be immediate if strictly accepted methods for catheterization are not available. A high suprapubic cystostomy with tidal drainage affords the best type of care. With an indwelling catheter urethritis is always present and extension of ascending infection is by direct lymphatic spread through the perirethral lymphatics to the kidney. There is no such communication between the suprapubic catheter and the kidneys and ascending infection is less common from a bladder which is draining freely. As soon as an automatic bladder becomes established on tidal drainage the small high suprapubic cystostomy wound closes rapidly and spontaneously, whereas closure of a low lying cystostomy is prolonged and requires excision. Infection, recumbency and dilatation of the upper urinary tract are important factors in the production of renal calculi. Since these do not disappear on ambulation their removal must be surgical. Vesical calculi can occasionally be dissolved by the use of the Albright Saby solution in the suprapubic tidal drain.

WHITTERIDGE. With distention of the bladder in patients having a complete cervical or high thoracic (above T₆) spinal cord lesion there is a tendency toward marked vasoconstriction with a rise in the blood pressure, a sharp drop in the pulse rate, a great

increase in volume of the pulse, and a rise in the temperature of the ear. With a lesion at or below T₆ there is a slight rise in the blood pressure, a drop in the pulse rate and volume, and a decrease in the temperature of the legs. In the latter group of cases vasomotor regulation is possible because there still is a large vascular bed which can be used by the vasomotor center for compensatory dilatation. With lesions above T₆ the area controlled by the vasomotor center is greatly reduced. There is no doubt that this phenomenon is due to a spinal reflex.

JOHNSON. Rehabilitation is less difficult in paraplegics with more distal cord lesions than in paraplegics with complete cervical or high thoracic cord transections because of the fewer vasomotor disturbances in the former group. In the higher level type of case the patient exhibits much more profound and lasting effects upon assuming an upright position than in the low level type. This is due to a cerebral anemia which is secondary to the drop in blood pressure associated with the higher cord lesions.

RUSSELL. Neither the neurologist nor the orthopedic surgeon alone can adequately deal with the care and rehabilitation of paraplegics, and the argument for their segregation into special centers is indisputable.

RICHARD C. SCHREIBER, M.D.

Legier L., and Coste M.: Recurrent Syncope Associated with Sinus Hyperactivity. Cure by Denervation of the Carotid Sinus. (*Syncope à répétition liées à une hyperactivité sinusale. Guérison par dénervation sino-carotidienne.*) *Presse méd.* 1947 55 174.

A 62 year old male presented himself stating that for the past 15 months he had been experiencing episodes varying from simple syncope with slight dyspnea and bradycardia, to severe periods of unconsciousness, occasionally with convulsions. When unconscious there was often complete cessation of the pulse and respiration. He never experienced incontinence or tongue biting and was able to tell when these episodes were approaching. The attacks were precipitated by any effort, such as sitting, changing position, defecating, urinating. Because of this illness the patient was forced to follow an extremely rigid way of life by discontinuing all activity and residing at home. Even these severe restrictions did not completely stop all the episodes or their equivalents.

Empirically, warm compresses on the neck were found to be of greatest value, more so than various stimulating drugs. Numerous clinical and laboratory examinations with particular attention to the cardiac status, showed no abnormalities. The blood pressure was 130/80. Many medical treatments were attempted, but none proved successful. Iodides, adrenalin, atropine, digitalis, atrophanthin, acetylcholine, theophylline, vitamin B, and various diets. The diagnosis was verified by the following maneuver:

The patient attempted to sit up. This caused marked syncope with loss of consciousness and cessa-

tion of the pulse and respiration which resumed slowly after several minutes. Pressure over the left carotid sinus caused the unconsciousness to reappear and the pulse rate to slow. Pressure on the right, to the contrary produced no effect. During one of these episodes the left carotid sinus was injected with novocaine with immediate return of consciousness.

Treatment was instituted by infiltrating the left carotid sinus with novocaine and denervating it. Atropine was given before the operation. Following this procedure the patient no longer presented any of the former reactions and at the time of writing had had no recurrences.

This syndrome was first described by Tschermak in 1886 who noted that pressure on the right lateral aspect of the neck in a patient caused a sensation of weakness, vertigo and slowing of the pulse. To date, more than 100 clinical cases have been published. The crisis is characterized by vertigo, sweating, loss of consciousness, pallor, apnea, cessation of pulse, hypotension, occasionally convulsions and rarely incontinence. One death has been reported due to compression of the carotid sinus. Transitory and permanent hemiplegias have occurred. The syndrome has been noted in many various forms, and minor equivalents have been described as simple syncope, vertigo, malaise, and mild anxiety.

The syndrome is precipitated by traumatism often only slight. It can be produced by the constriction of a tight collar by shaving and less frequently by simple cervical hyperextension or the hyperextension when lying in a lateral supine position. Certain instances have appeared with carotid tumors; their excision abolished the symptoms. Often, no precipitating reason can be found and it is hypothesized that the sinus is stimulated by a sudden rise in the blood pressure in response to exertion or some hormonal secretion. The definitive diagnosis is established by production of the syndrome by compression of the carotid sinus and of its abolition by infiltration of this region.

A definite etiology of carotid sinus hyperactivity cannot be given at present, although arteriosclerosis has been suggested. The carotid sinus is often affected by arteriosclerosis and this pathological change may disturb its normal functioning.

According to Ferris, Capps, Weiss, and Munro whose observations were based on 52 cases, 3 different types of hyperactivity have been distinguished.

1. The vagal type seen in one third of the cases. The symptoms are related to a sinoauricular or an atriocentric heart block which causes a cerebral anemia. Adrenalin or atropine prevents the attack. This syndrome is relieved by medical treatment.

2. The depressor type, rarely found. Stimulation of the carotid sinus causes a generalized venous dilatation with a secondary hypotension. These symptoms respond to adrenalin but are not in-

fluenced by atropine. Other stimulants such as ephedrine and benzedrine are helpful. Denervation of the sinus is indicated in this type.

3. The cerebral type observed in two-thirds of the cases. Sinus stimulation appears to cause hypothalamic activity. Atropine and adrenalin have no effect. This syndrome is not helped by medical treatment and should be treated exclusively by surgery (denervation of the sinus).

Operation should be done under local anesthesia only after preoperative administration of atropine and novocaine infiltration of the carotid sinus. This is to prevent the carotid sinus syndrome from recurring during operation. It is rarely that the denervation needs to be done bilaterally. In the 28 cases collected from the literature, surgery was done unilaterally in 25 instances with definitive cure in 65 per cent. C. FARNSWICK KITTLE, M.D.

MISCELLANEOUS

Poppen J. L., and Lemmon C.: The Surgical Treatment of Hypertension. *J. Am. M. Ass.* 1947 134: 1.

The authors report a consecutive series of 100 cases of hypertension treated by an extensive thoracodorsal sympathectomy from the third or fourth thoracic through the second lumbar ganglia. This was done to attain more permanent and immediate lowering of the blood pressure than they had apparently achieved by the Smithwick operation.

The operative procedure was carried out through a curvilinear incision from the sixth rib to the border of the twelfth rib. A 4 cm. portion of the eighth and eleventh ribs was resected and the chain was resected without incision of the diaphragm. The operation was performed under high spinal anesthesia supplemented with sodium pentothal.

The most important problem in regard to sympathectomy lies in the proper selection of the patients. Although definite criteria are lacking, a correlation of the various tests and the clinical impression will help to rule out many patients that would not be benefited. The contraindications are as follows: cardiac failure, renal failure, and severe retinal arteriosclerosis with a fixed blood pressure. Patients with early and mild hypertension were not operated upon. Considerable caution was exercised in the selection of patients with a previous coronary thrombosis, angina pectoris, auricular fibrillation, or gallop rhythm. Cerebrovascular episodes in an otherwise suitable candidate were not considered a contraindication to surgery. The most suitable candidates were those under 50 years of age with definite progression of the hypertension, ocular fundi of grades 2, 3, or 4 (Keith, Wagener and Barker) and in whom the examination did not reveal any of the contraindications already mentioned.

The interpretation and evaluation of results were modified slightly in that a normal blood pressure in an otherwise incapacitated patient was not considered a good result, but a blood pressure slightly

above the accepted level of 150 mm. systolic and 100 mm. diastolic in a patient in excellent health was considered a good result. Although the authors realize the inadequacy of using the blood pressure level as a criteria, there is no other scientific measuring rod at present. The results are quoted as follows: good, 4 per cent; fair, 21 per cent; and unsatisfactory, 22 per cent. Six patients died after dismissal from the hospital but there was only a 1 per cent surgical mortality. A rather surprising finding was that the known duration of the hypertension did not influence the results of the sympathectomy. Although the greater number of patients had their hypertension less than 5 years the results were not appreciably better in these than they were in the patients with hypertension of longer duration.

An apparently worthwhile innovation is the practice to perform a unilateral sympathectomy when a nephrectomy performed in the presence of hypertension. If the blood pressure drops to normal, the patient is dismissed for follow up; however if no improvement ensues the second stage sympathectomy is then performed. JACK I. WOOLF, M.D.

Palmer, R. S. *The Surgical Treatment of Hypertension.* *J Am Med Ass* 94 349.

The author reports his evaluation of sympathectomy for hypertension from the standpoint of a medical observer. The effect upon the blood pressure was considered as the most important criterion. The upper limits of the normal blood pressure were considered as 150 mm. Hg. systolic and 100 mm. Hg. diastolic. After 5 years only 18 per cent of 74 patients treated by supradiaphragmatic sympathectomy had a normal or near normal blood pressure, the favorable results occurring largely in hypertension of grades 1 and 2. The results were much improved after Smithwick extended the resection of the sympathetic chain from above the ninth dorsal ganglion to below the second lumbar ganglion.

A 1 year followup of 49 patients who underwent the thoracodorsal sympathectomy revealed that 53 per cent had a normal blood pressure. The patients with hypertension of grades 1, 2, and 4 obtained the better results.

After 3 years a follow-up study of 63 sympathectomized patients gave the following results: 50 per cent were dead, 45 per cent had failed to obtain a satisfactory blood pressure response, and 25 per cent had maintained normal or near normal blood pressures. The patients that may have obtained a partial drop in blood pressure with subjective improvement were not listed. In comparing these figures

with a medical series, it was found that 30 per cent of the latter had expired. A group of 100 patients maintained on a general medical regimen plus potassium thiocyanate revealed that under the best conditions of medical treatment a sustained normal blood pressure could be effected in only 12 per cent of the patients.

A study of the surgical group failed to reveal a definite guide as to the selection of patients. However the following facts were noted: (1) in a greater proportion of the successes the blood pressure would approach the normal levels spontaneously; (2) high maximum levels of diastolic pressure were more frequent in the unsuccessful cases; (3) the relative test resulted in a drop to normal in 7 of 14 successful cases and in 4 of 13 unsuccessful cases; and (4) the pulse pressure groupings had no significance. In general, it is stated that women and younger patients with less evidence of organic changes have better chances of obtaining good results.

Although 5 per cent of the definite successes occurred in cases of hypertension of grades 1 and 2, the most important observation pertained to the 11 cases in the malignant hypertensive group. Three patients who obtained normal pressures are alive and working 1 for 3 years and 2 for about 5 years. Two failed to obtain a drop in blood pressure but are active and working 1 for 3 years and the other for 5 years. These are certainly outliving their life expectancy. The remaining 6 patients have died but all had either renal or cardiac damage, or both. It would be of interest to know whether any of these had obtained a satisfactory blood pressure response to surgery.

An important phase of sympathectomy pertains to the various physiologic effects, disabilities, and dangers. A 1 per cent mortality rate was found in this series and it compared favorably with other groups. Complications of surgery are the development of extrapleural fluid, pneumothorax, and basal atelectasis; however these are usually overcome easily. Postoperative neuritis is frequent and may last from a few weeks to several months. Postural hypotension with compensatory phenomena, such as tachycardia and breathlessness, may persist for several months and to a lesser degree for longer periods of time.

Despite the fact that only a fourth of the patients were deemed to have received the maximum benefit of a maintained normal blood pressure, "perhaps 60 per cent" showed a persistent improvement in the general level of their blood pressure.

JACK I. WOOLF, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Hopkins, F. S., and Egnatz, N. Carcinoma of the Breast. *N. England J. M.* 1947 336 330.

The routine procedure at the time of the first visit of a patient with suspected cancer of the breast consisted in taking x-ray films of the chest as well as of the upper ends of the humeri, the skull, the spine, and the pelvis including the upper ends of the femurs. Unsuspected metastases have been found in several cases that would otherwise have been deemed operable. Other contraindications that have been found are fixed matted lymph nodes in the axilla and definite inflammatory carcinoma. If there was any suspicion of involvement of the supradavicular nodes, a biopsy was first done.

The patient's general condition was not considered as a contraindication to operation although most of the simple mastectomies were done because of poor physical condition. There were deaths in 3 cases after radical operations and 1 death following a simple mastectomy—all in patients over 75 years of age and in poor physical condition. Since then, cases in the older age group were carefully evaluated and only referred for radiation therapy if there was a life expectancy of at least 5 years. After this procedure had been adopted there were no postoperative deaths.

Most operations began with a local excision of the tumor and a frozen section to confirm the diagnosis. A formalin-soaked sponge was placed in the cavity before suture was done, and the wound was sealed with collodion and gauze. The usual incision was of the Rodman-Greenough type. The important feature is to make the incision include an area of skin at least as wide as the breast and with the tumor at least 5 cm. from the incision. After the pectoral muscles have been divided at their insertion, a meticulous dissection of the axilla is made all areolar tissue being removed from the axillary vein. The upper rectus fascia is removed with the breast, muscles, and axillary contents. Wide under-cutting usually permits closure without grafting. The cure rate for radical mastectomies was in direct proportion to the duration of the operation. The procedures lasting less than an hour amounted to 28.6 per cent, whereas for each successive hour of operating time they amounted to 35.3 34.3 43.7 and 56.3 per cent respectively.

Preoperative x-ray treatment was not used but all patients with axillary metastases were given postoperative radiation. Women who were still menstruating were offered ovarian radiation.

In the determination of the results the operative deaths and patients alive with recurrences were classed as failures. Of the 70 patients who had radical operations 30 or 43 per cent, are living and well, without evidence of cancer. Of the 45 cases

with axillary metastases 1.4, or 31 per cent, are considered 5 year cures. Sixteen of 25 patients or 64 per cent, with no involvement of the axillary lymph nodes, are living and well. It is the authors' opinion that complete radical operation should be done at the time of the first surgical approach to a cancer of the breast.

The following are considered definite contraindications to operation: distant metastases, inflammatory carcinoma, supradavicular metastases, edema of the arm, intercostal or parasternal nodules, satellite nodules in the skin over the breast, extensive edema of the skin and carcinoma developing during pregnancy and lactation. Other factors of such poor prognostic significance that the presence of any two is regarded as a contraindication to operation include ulceration of the skin, limited edema of the skin (less than a third) fixation of the tumor to the chest wall, axillary lymph nodes measuring 2.5 cm. or more in the transverse diameter, fixation of the axillary lymph nodes to the skin or the deep structures of the axilla, and metastases in the nodes proved by biopsy.

The percentage of lymph node involvement and the microscopical grade of the tumor are of aid in making a prognosis. X-ray treatment is of great help in making the patient more comfortable.

LEE PULLER, M.D.

TRACHEA, LUNGS, AND PLEURA

Adams, R. and Picarra, B. J.: Bronchiectasis. *J. Am. R. Ass.* 1947 134 240.

This is a report of 50 consecutive surgically treated cases of bronchiectasis at the Lahey Clinic in the 5 year period ending August 31, 1945. There were no deaths in the series, which showed that bronchiectasis may be cured and functional usefulness restored by appropriate pulmonary resection.

Bronchiectasis is an important pathological entity from a socioeconomic viewpoint. A chronic illness will alter the personality and influence the character and career of an individual. Persons with this disease are branded as having tuberculosis. Children's schooling is neglected because their illness renders them unable to keep pace with their classmates. When the teens are reached antisocial patterns are more clearly defined and in the 20's and early 30's increasing responsibilities of life and decreasing recuperative powers lead to frequent break-downs.

No one etiologic agent can be found for bronchiectasis. Among the common contributing causes are (1) diseases of the accessory air passages (2) acute infections of the upper respiratory tract or infectious diseases (3) congenital malformations such as cystic disease of the lung; (4) bronchial obstruction due to a foreign body, hyperplasia of the

mediastinal nodes or tumor (5) emphysema or atelectasis and (6) situs inversus and sinusitis. From these it can be seen that the basic mechanisms in the development of bronchiectasis are infection of the bronchial wall and bronchial obstruction.

In some cases following pneumonia, x ray evidence of bronchiectasis appears and disappears in 1 or 2 months as silently as it developed. This is called "pseudobronchiectasis" or "transitory bronchiectasis."

Initially infection causes hyperemia and thickening of the mucosa. Eventually highly vascular papillary projections of the mucosa protrude into the lumen. From dilatation peripheral to an obstruction, cylindrical bronchial enlargement or ca. titation is produced. Later the lung parenchyma is replaced by fibrous tissue. When the cavities become infected, purulent material accumulates. If putrefactive organisms invade secondarily the sputum odor is foul. Occasional pulmonary abscesses form.

Histologically one sees inflammation, proliferation, and tissue destruction. The bronchial wall is infiltrated with leucocytes and lymphocytes. If the disease is chronic, the glands, elastic tissue, muscle fibers and even cartilage may be replaced by fibrous tissue. The epithelial continuity may be broken but it is the last to be destroyed. Blood vessels in the wall may rupture or become thrombosed (if infected, a metastatic brain abscess may result). The adjacent pulmonary tissue becomes infected and, later fibrotic. There are peripheral zones of compensatory emphysema.

In congenital bronchiectasis the lung contains many cystlike cavitations lined by a layer of flattened or cuboidal epithelium often ciliated. This pathologic entity may be called congenital cystic disease of the lung.

Bronchiectasis may involve one or more bronchopulmonary segments within a lobe or it may be multilobar. The basal division of the lower lobes is most frequently involved as opposed to lung abscess which usually occupies the dorsal division of the lower lobe. The anatomic pattern is static, and the disease does not spread from lobe to lobe. This justifies the rationale of resection of the involved bronchopulmonary segment. Most of the unsatisfactory results are due to failure to appreciate the high incidence of residual disease in an unresected lingula.

Clinically one may see a chronic uncontrollable productive cough, foul breath, hemoptysis, purulent sputum, chest pain and dyspnea on exertion. Symptoms are usually more evident in the morning.

Physical signs vary with the extent of secondary infection and atelectasis. Dullness, diminished breath sounds, and moist rales are positive findings over the involved segments. Clubbed fingers are common in long standing disease.

The x-ray findings of collapse, dilated bronchi, and compensatory expansion of the adjacent pulmonary tissue are characteristic. Fluoroscopic and lateral views are desirable. Bronchography is rarely neces-

sary for diagnosis but is necessary for determining the extent of the process prior to surgical attack.

Patients under 50 with unilateral disease limited to one collapsed lobe, with infection temporarily quiescent, and who otherwise are in good physical condition constitute the best candidates for surgical treatment. Patients with diminished respiratory reserve, bilateral disease, advanced emphysema and fibrosis, chronic asthma, and chronic pulmonary suppuration are greater surgical risks.

Operation should be carried out only when the patient is in the best physical condition. He is given a nutritious diet supplemented by vitamins and iron, daily periods of rest and graded exercise and postural drainage supplemented by bronchoscopic aspirations when necessary. Associated pleural infections are drained dependently until active infection is minimized. Sinus disease is eradicated. Sulfonamide or penicillin (by muscular injection or inhalation) is given preoperatively to reduce infection.

The operative technique stresses gentle careful dissection to complete incomplete fissures. The hilar vessels are individually exposed and tied. The bronchus should be closed in meticulous fashion with 2 rows of fine interrupted silk stitches, the posterior membranous portion being folded into the anterior cartilaginous portion and the stump being buttressed with a free fascial graft or a pedicled flap of parietal pleura. The tomniquet technique is no longer used.

After operation, measures are employed to prevent shock, anoxemia, or failure of complete lung expansion. Fluid formation in the pleural space should be prevented or removed and obstruction of the bronchial tree must be prevented. Blood transfusions and oxygen therapy are routine. Opiates are used sparingly and voluntary coughing to clear secretions is encouraged. Negative intrathoracic pressure is maintained by a drainage catheter which is usually removed in 5 days. Bronchoscopic aspiration is used when indicated. Prophylactic use of penicillin is continued for about 1 week. Infection and emphysema are the common complications. Effective stump closure, the use of sulfonamides or penicillin, and the complete re-expansion of the remaining lobe or lobes aid in eradicating postoperative infection.

Forty-five of the patients contracted the disease before the fifth decade. In 50 per cent the duration of symptoms was from 1 to 5 years, in 30 per cent from 5 to 10 years, and in 20 per cent from 10 to 20 years. Associated infections of the accessory nasal sinuses or of the respiratory system were present in nearly all of the patients. There were 31 women and 19 males in this series.

All 50 patients were treated by pulmonary resection. In 19 cases the disease was on the right side in 31 on the left, and in 5 bilateral involvement was present. One pneumonectomy was done, bilobectomies were done in 18 cases. The lingula was affected in 43.3 per cent of the cases.

All of the patients received intratracheal anesthesia with cyclopropane-ether. There were 3 postoperative emphysemas requiring drainage, 1 persistent

bronchopleural fistulas and 1 thrombophlebitic complication. In this series followups from 1 month to 5 years were carried out and all but 2 patients with contralateral disease are in good health. There were no deaths.

The prognosis following pulmonary resection is favorable. Almost all of the patients were cured or significantly benefited. Forty-two of the 50 have been able to resume normal activity. From this study it can be concluded that beneficial surgical results indicate the inefficiency of medical treatment. True cure can be obtained only by resection of the diseased lung tissue. Other treatment only results in symptomatic relief. Surgery should be advised early in the disease.

ROBERT R. BIZZLOW, M.D.

Ochsner, Alton; DeBaKey, Michael; and Dixon, Leonard: Primary Pulmonary Malignancy Treated by Resection. *Ann Surg* 1947 125 533

Ochsner and his associates present a very completely detailed analysis of 360 cases of carcinoma of the lung observed during the 11 year period from 1936 to 1946 inclusive.

Twenty-seven charts add greatly to the lucidity of the presentation. Of the total 360 cases 129 were resected. Among these were 124 cases of bronchogenic carcinoma, 2 of fibrosarcoma and 1 case each of melanosis, neurogenic sarcoma and lymphoblastoma.

Lung carcinoma was encountered over twice as frequently among white as among colored persons.

Eighty-six per cent of the lung carcinomas were in males. (In 6,769 collected cases 79 per cent were in males; adenomas however are slightly more frequent in females.) Primary cancer of the lung is exceeded only by primary cancer of the stomach in males.

The great majority of cases (over 87%) occurred in patients between the ages of 40 and 70 years. Among the 129 resected cases no significant etiologic factor was found. Neither occupation nor smoking seemed to be of etiologic significance.

The clinical picture is not sharply characteristic and the onset is insidious. The most common symptoms were as others have found: cough, weight loss, discomfort in the chest and hemoptysis, in that order. In many of the early cases only one or two of these symptoms were present. Early physical findings are likely to be negative. Seventy-six cases were found in the right lung and 53 in the left. The upper lobes on each side and the right lower lobe were involved in practically the same incidence.

Positive roentgen diagnosis was made in 81 per cent of the cases. Bronchoscopy was done in 112 cases. In 17 of the 129 cases x rays showed the tumor to be so peripheral that bronchoscopy was not done. Biopsy was obtained in 61 per cent. Eighty-one per cent of these cases were positive. Aspiration biopsy is condemned because of the danger of pleural implantation; the authors had 2 such cases. Exploration for diagnosis is obligatory if carcinoma of the lung cannot be positively excluded by other means.

Pneumonectomy by anterior approach is the treatment of choice. Operability is discouragingly low and resectability even lower: among 29 per cent of 2,034 cases of primary malignancy from the literature operation appeared feasible but resection was possible in only 13.4 per cent. The more recent reports show a trend toward higher incidence and of the 360 cases reported 58 per cent were explored and 36 per cent resected.

Among the 360 cases of pulmonary malignancy diagnosed clinically 109 or 30 per cent were clearly inoperable. Of the 251 patients regarded as operable 41 or 16 per cent refused surgery. Of the 210 cases explored 81, or 38 per cent proved inoperable leaving 129 (61% of those explored or 36% of the total series) in which resection could be done.

Postoperative infection (empyema) occurred in 15 of the 129 cases, or 11.6 per cent. In 5 instances (3.8%) the infection was the result of a blown bronchus. Ten of the patients with postoperative infection died. Chemotherapy in the authors' hands has not materially influenced the morbidity in postoperative infection.

Among the 81 cases explored but not resected there were 14 hospital deaths (17.3%). In the resectable group of 129 there were 32 hospital deaths (24.8%). The total operative mortality risk then was 22 per cent. Although the operative mortality was high the mortality in absence of operation is 100 per cent.

Prior to 1942 the hospital mortality was 44.5 per cent and since 1942 it was 10.6 per cent. The average postoperative hospital stay prior to 1942 was 32 days and after 1942 13 days.

Of the 107 patients resected only a little over one-half (54%) survived 6 months. Six (5.6%) of 27 resected patients were alive at the end of 5 years. When hospital deaths were excluded the survival rate of those operated 5 years or more ago was 40 per cent. None with extension of the lesion survived longer than 4 years after operation. If only those with localized lesions were included the 5 year survival rate was 50 per cent. If a person lives through the third year after operation he has a very good chance of being alive at the end of 5 years; for the distribution curve of survival rate by the third year has been stabilized and continues almost as a plateau until the fifth year.

Among the 107 patients resected 38.7 per cent had extension at the time of resection.

When survival rates were calculated according to the year of operation it was found that the rate of survival in each postoperative year improved after 1942 as compared to before 1942. This perhaps reflects improvements in technique. This improvement is shown in patients both with and without localization of the malignancy.

At the present time only 36 per cent of the patients with clinical cases of carcinoma of the lung are resectable and of these only 8 per cent survive 5 years or more. Twenty-two per cent could enjoy a 5 year survival if diagnosis was made early enough to permit resection.

FRANK B. QUINN, M.D.

mediastinal nodes, or tumor (5) emphysema or atelectasis and (6) situs inversus and sinusitis. From these it can be seen that the basic mechanisms in the development of bronchiectasis are infection of the bronchial wall and bronchial obstruction.

In some cases following pneumonia, x-ray evidence of bronchiectasis appears and disappears in 1 or 2 months as silently as it developed. This is called "pseudobronchiectasis" or "transitory bronchiectasis."

Initially infection causes hyperemia and thickening of the mucosa. Eventually highly vascular papillary projections of the mucosa protrude into the lumen. From dilatation peripheral to an obstruction cylindrical bronchial enlargement or cavitation is produced. Later the lung parenchyma is replaced by fibrous tissue. When the cavities become infected purulent material accumulates. If putrefactive organisms invade secondarily, the sputum odor is foul. Occasional pulmonary abscesses form.

Histologically one sees inflammation, proliferation and tissue destruction. The bronchial wall is infiltrated with leukocytes and lymphocytes. If the disease is chronic, the glands, elastic tissue, muscle fibers, and even cartilage may be replaced by fibrous tissue. The epithelial continuity may be broken but it is the last to be destroyed. Blood vessels in the wall may rupture or become thrombosed (if infected, a metastatic brain abscess may result). The adjacent pulmonary tissue becomes infected and, later fibrotic. There are peripheral zones of compensatory emphysema.

In congenital bronchiectasis the lung contains many cystlike cavitations lined by a layer of flattened or cuboidal epithelium often dilated. This pathologic entity may be called congenital cystic disease of the lung.

Bronchiectasis may involve one or more bronchopulmonary segments within a lobe or it may be multifocal. The basal division of the lower lobes is most frequently involved as opposed to lung abscess which usually occupies the dorsal division of the lower lobe. The anatomic pattern is static, and the disease does not spread from lobe to lobe. This justifies the rationale of resection of the involved bronchopulmonary segment. Most of the unsatisfactory results are due to failure to appreciate the high incidence of residual disease in an unresected lingula.

Clinically one may see a chronic uncontrollable productive cough, foul breath, hemoptysis, purulent sputum, chest pain and dyspnea on exertion. Symptoms are usually more evident in the morning.

Physical signs vary with the extent of secondary infection and atelectasis. Dullness, diminished breath sounds and moist rales are positive findings over the involved segments. Clubbed fingers are common in long-standing disease.

The x-ray findings of collapse, dilated bronchi and compensatory expansion of the adjacent pulmonary tissue are characteristic. Fluoroscopy and lateral views are desirable. Bronchography is rarely neces-

sary for diagnosis but is necessary for determining the extent of the process prior to surgical attack.

Patients under 50 with unilateral disease limited to one collapsed lobe with infection temporarily quiescent, and who otherwise are in good physical condition constitute the best candidates for surgical treatment. Patients with diminished respiratory reserve, bilateral disease, advanced emphysema and fibrosis, chronic asthma and chronic pulmonary suppuration are greater surgical risks.

Operation should be carried out only when the patient is in the best physical condition. He is given a nutritious diet supplemented by vitamins and iron, daily periods of rest and graded exercise and postural drainage supplemented by bronchoscopic aspirations when necessary. Associated pleural infections are drained dependently until active infection is minimized. Sinus disease is eradicated. Sulfonamide or penicillin (by muscular injection or inhalation) is given preoperatively to reduce infection.

The operative technique stresses gentle careful dissection to complete incomplete fissures. The hilar vessels are individually exposed and tied. The bronchus should be closed in meticulous fashion with 2 rows of fine interrupted silk stitches, the posterior membranous portion being folded into the anterior cartilaginous portion and the stump being buttressed with a free fascial graft or a pedicled flap of parietal pleura. The tourniquet technique is no longer used.

After operation, measures are employed to prevent shock, anoxemia, or failure of complete lung expansion. Fluid formation in the pleural space should be prevented or removed and obstruction of the bronchial tree must be prevented. Blood transfusions and oxygen therapy are routine. Opiates are used sparingly and voluntary coughing to clear secretions is encouraged. Negative intrathoracic pressure is maintained by a drainage catheter which is usually removed in 3 days. Bronchoscopic aspiration is used when indicated. Prophylactic use of penicillin is continued for about 1 week. Infection and emphysema are the common complications. Effective stump closure, the use of sulfonamides or penicillin, and the complete re-expansion of the remaining lobe or lobes aid in eradicating postoperative infection.

Forty-five of the patients contracted the disease before the fifth decade. In 50 per cent the duration of symptoms was from 1 to 5 years, in 30 per cent from 5 to 10 years, and in 20 per cent from 10 to 20 years. Associated infections of the accessory nasal sinuses or of the respiratory system were present in nearly all of the patients. There were 31 women and 19 males in this series.

All 50 patients were treated by pulmonary resection. In 19 cases the disease was on the right side, in 31 on the left, and in 5 bilateral involvement was present. One pneumonectomy was done, bilobectomies were done in 18 cases. The lingula was affected in 43.3 per cent of the cases.

All of the patients received intratracheal anesthesia with cyclopropane-ether. There were 5 post-operative emphysemas requiring drainage, 3 persistent

bronchopleural fistulas, and 1 thrombophlebitic complication. In this series followups from 1 month to 5 years were carried out, and all but 2 patients with contralateral disease are in good health. There were no deaths.

The prognosis following pulmonary resection is favorable. Almost all of the patients were cured or significantly benefited. Forty two of the 50 have been able to resume normal activity. From this study it can be concluded that beneficial surgical results indicate the inefficiency of medical treatment. True cure can be obtained only by resection of the diseased lung tissue. Other treatment only results in symptomatic relief. Surgery should be advised early in the disease.

ROBERT R. BRONLOW M D

Ochaner Alton; DeBailey Michael; and Dixon Leonard Primary Pulmonary Malignancy Treated by Resection *Ann. Surg.*, 1947 125 532

Ochaner and his associates present a very completely detailed analysis of 360 cases of carcinoma of the lung observed during the 11 year period from 1936 to 1946 inclusive.

Twenty-seven charts add greatly to the lucidity of the presentation. Of the total 360 cases 129 were resected. Among these were 124 cases of bronchogenic carcinoma, 2 of fibrosarcoma and 1 case each of melanomasarcoma, neurogenic sarcoma and lymphoblastoma.

Lung carcinoma was encountered over twice as frequently among white as among colored persons.

Eighty six per cent of the lung carcinomas were in males. (In 6769 collected cases 79 per cent were in males adenomas however are slightly more frequent in females.) Primary cancer of the lung is exceeded only by primary cancer of the stomach in males.

The great majority of cases (over 87%) occurred in patients between the ages of 40 and 70 years. Among the 129 resected cases, no significant etiologic factor was found. Neither occupation nor smoking seemed to be of etiologic significance.

The clinical picture is not sharply characteristic and the onset is insidious. The most common symptoms were, as others have found, cough, weight loss, discomfort in the chest, and hemoptysis in that order. In many of the early cases only one or two of these symptoms were present. Early physical findings are likely to be negative. Seventy-six cases were found in the right lung and 53 in the left. The upper lobes on each side and the right lower lobe were involved in practically the same incidence.

Positive roentgen diagnosis was made in 81 per cent of the cases. Bronchoscopy was done in 112 cases. In 17 of the 129 cases, x rays showed the tumor to be so peripheral that bronchoscopy was not done. Biopsy was obtained in 61 per cent. Eighty-one per cent of these cases were positive. Aspiration biopsy is condemned because of the danger of pleural implantation the authors had 2 such cases. Exploration for diagnosis is obligatory if carcinoma of the lung cannot be positively excluded by other means.

Pneumonectomy by anterior approach is the treatment of choice. Operability is discouragingly low and resectability even lower, among 29 per cent of 2034 cases of primary malignancy from the literature operation appeared feasible but resection was possible in only 13.4 per cent. The more recent reports show a trend toward higher incidence and of the 360 cases reported 58 per cent were explored and 36 per cent resected.

Among the 360 cases of pulmonary malignancy diagnosed clinically 109 or 30 per cent, were clearly inoperable. Of the 251 patients regarded as operable 41 or 16 per cent refused surgery. Of the 210 cases explored 81, or 38 per cent proved inoperable, leaving 129 (61% of those explored or 36% of the total series) in which resection could be done.

Postoperative infection (empyema) occurred in 15 of the 129 cases, or 11.6 per cent. In 5 instances (3.8%) the infection was the result of a blown bronchus. Ten of the patients with postoperative infection died. Chemotherapy in the authors hands has not materially influenced the morbidity in post operative infection.

Among the 81 cases explored but not resected, there were 14 hospital deaths (17.3%). In the resectable group of 129 there were 32 hospital deaths (24.8%). The total operative mortality risk then was 22 per cent. Although the operative mortality was high the mortality in absence of operation is 100 per cent.

Prior to 1942 the hospital mortality was 44.5 per cent and since 1942 it was 10.6 per cent. The average postoperative hospital stay prior to 1942 was 32 days and after 1942 13 days.

Of the 107 patients resected only a little over one-half (54%) survived 6 months. Six (22%) of 27 resected patients were alive at the end of 5 years. When hospital deaths were excluded the survival rate of those operated 5 years or more ago was 40 per cent. None with extension of the lesion survived longer than 4 years after operation. If only those with localized lesions were included the 5 year survival rate was 50 per cent. If a person lives through the third year after operation he has a very good chance of being alive at the end of 5 years, for the distribution curve of survival rate by the third year has been stabilized and continues almost as a plateau until the fifth year.

Among the 107 patients resected 38.7 per cent had extension at the time of resection.

When survival rates were calculated according to the year of operation it was found that the rate of survival in each postoperative year improved after 1942 as compared to before 1942. This perhaps reflects improvements in technique. This improvement is shown in patients both with and without localization of the malignancy.

At the present time only 36 per cent of the patients with clinical cases of carcinoma of the lung are resectable and of these only 8 per cent survive 5 years or more. Twenty two per cent could enjoy a 5 year survival if diagnosis was made early enough to permit resection.

FRANK B. QUINN M D

Rienhoff, William F. Jr.: *The Present Status of the Surgical Treatment of Carcinoma of the Lung.* *Ann. Surg.* 1947 125 341

Three hundred and twenty-seven patients with carcinoma of the lung have been operated upon since the first pneumonectomy was performed at Johns Hopkins Hospital 13 years ago. Total pneumonectomy was done in 112 (34%) but 115 (66%) were inoperable at time of exploration.

There was no operative mortality from exploration alone. The operative mortality from pneumonectomy (all deaths occurring within 1 month of operation regardless of cause were included) was 22 per cent. The postoperative mortality from pneumonectomy has improved from 27 per cent prior to 1939 to 21 per cent since 1939.

Twelve patients have survived 5 years or more. While the statistics presented do not present an accurate calculation of the 5 year survival rate approximately 30 per cent of the patients subjected to pneumonectomy prior to 1941 (40) survived 5 years, or about 9.4 per cent of the 128 patients explored or pneumonectomized during this period.

Sixty-nine of the patients resected are now dead. However, these lived an average of a little over 1 year following pneumonectomy. (If the 25 postoperative deaths are excluded, longevity following pneumonectomy of the remaining 44 averages 1.6 years.) The 203 patients who were explored lived for an average of only 5 months following exploration. Thus longevity even in patients not cured is materially increased by resection.

In 70 per cent of the pneumonectomy cases there were metastases to the bronchial or tracheal lymph nodes. Sixty-five per cent of the cases were squamous cell carcinomas and 35 per cent were adenocarcinomas, including pleomorphic and oat cell cancers. The adenocarcinoma is the more malignant type. The cancer was near the hilus in 90 per cent and in the periphery (silent areas) in 10 per cent.

The roentgenograms were positive in every instance of the 327 cases. Positive biopsies were obtained in 70 per cent. The sex ratio was 6 to 1 in favor of the males. The right and left lungs were involved in about the same incidence.

Symptoms of cough were present in 71 per cent, hemoptyses in 63 per cent, and pain in 50 per cent. Exploratory thoracotomy "is imperative if a definite diagnosis cannot be obtained by other means."

The most important preoperative preparation is the induction of artificial pneumothorax to allow for adjustment of the cardiovascular system. One stage total pneumonectomy by the anterior approach is the operative procedure of choice. The bronchial stump is approximated with interrupted mattress sutures from 1 to 2 cm. proximal to the amputation and a pedicled flap of pleura is sutured over the viable stump. The stump lumen is cleared of blood clot or tumor tissue before closure and the patient is again examined with the bronchoscope before he leaves the table. Penicillin is used both preoperatively and postoperatively.

In the discussion RICHMOND also mentions 4 patients operated upon for solitary metastases, 3 by himself for metastatic fibrosarcoma from the tendon sheath of the thigh and 1 by Blalock for simple metastases from the colon. FRANK B. QUINN, M.D.

Domenico, P.: *Pleuropulmonary Sclerosis of the Apex* (Le cicatrici pleuro-polmonari dell'apice). *Minerva Med.*, Tor., 1947 38 343.

This discussion of the etiology and prognosis of cicatricial lesions of the apex is based on the histological studies of 5 patients dying of unrelated disease in whom no history of tuberculous infection was obtainable. In all of the cases the sections showed rather dense fibrous tissue with peripheral areas of emphysema. There were no traces of tuberculosis.

There is little doubt as to the tuberculous origin of these sclerotic areas and the absence of tuberculous elements excludes the possibility of re-exacerbation. EDWIN B. FARRINGTON, M.D.

HEART AND PERICARDIUM

Tausig, Helen B.: *Diagnosis of the Tetralogy of Fallot and Indications for Operation.* *J. Thorac. Surg.* 1947 16 34.

The four features which characterize the tetralogy of Fallot are pulmonary stenosis or atresia combined with dextroposition of the aorta, a high ventricular septal defect, and right ventricular hypertrophy.

The characteristic clinical findings are cyanosis and clubbing, a heart of normal size, usually a basal systolic murmur and a pure second sound. The electrocardiogram shows a right deviation. The x-ray shows an absence of the normal fullness of the pulmonary conus and clear lung fields. Fluoroscopy shows no pulsations at the hilus of the lungs.

There are many variables. The systolic murmur may be quite loud, or entirely absent. The second sound may be diminished or accentuated, it is never reduplicated. Cyanosis may be marked or slight, according to the degree of the oxygen unsaturation and the height of the red blood count. The oxygen saturation of arterial blood is also subject to great variation (from 88 to 10 per cent). It varies from individual to individual according to the severity of the pulmonary stenosis, and also in the same individual from day to day. The exercise tolerance of the individual shows a corresponding variation; some persons can walk a mile, some not at all. Operation is indicated for those who are severely handicapped.

The operation is designed to increase the circulation of the lungs. It consists of an anastomosis between the proximal end of one of the systemic vessels to the side of one of the main pulmonary vessels. The operation is indicated only in cases in which the primary difficulty is lack of circulation to the lungs. It is possible only when there is a pulmonary artery to which to anastomose the systemic artery and the pressure in the systemic artery is

THE new edition of *Cardiovascular Disease*¹ by Scherf and Boyd is a standard textbook. The authors have successfully covered a very extensive field in a single book of 455 pages. The material presented for the most part represents a conventional viewpoint of cardiology in the United States. The book is carefully printed, well organized, and satisfactorily indexed.

The chapter on myocarditis to which the authors call particular attention may cause some debate with their readers. The chapter on heart and endocrine disorders might also provoke some discussion. Particular reference might be called to the presumed effect of estrogens upon the electrocardiogram. The pages on irradiation of autonomic reflexes to and from the heart although short, is particularly interesting.

On the whole this book is to be recommended as a standard text in cardiovascular disease.

CHADWICK C. MARRER.

THE third edition of Greenblatt's *Office Endocrinology*² represents a revision and enlargement of the material presented in the first two editions. The author considers all the glands of internal secretion but the real emphasis, indeed the real value of the book lies in its comprehensive treatment of the problems concerned in female endocrinology. The presentation is intended as a guide to the endocrine problems which the general practitioner and the gynecologist may meet in their everyday practice. It is concise in its expression and does not include a great deal of theoretical material. The emphasis is on therapy, and a section on hormoneology includes a list and a discussion of many of the available estrogens, androgens, progestational hormones, adrenal cortical hormones, and pituitary hormones. There is a small section on male endocrinology. In the opinion of the reviewer this book should prove of considerable value to the general practitioner in the treatment of such endocrinopathies as amenorrhea, dysmenorrhea, menometrorrhagia, and the climacteric. There is a very good discussion of such diagnostic adjuncts as the vaginal smear, endometrial suction curettage, and the more recent pregnancy tests. The diagnostic and therapeutic principles expressed are sound and should contribute much to the understanding and treatment of endocrine problems which are always among the most complex encountered not only by the general practitioner but by the gynecologist as well.

STUART AXEL.

THE purpose in publishing at this time, *Progress in Gynecology*³ a 552 page volume, was "to refresh and bring up to date those medical men who have

spent the last years in the armed forces of their country and who have been removed from the practice of the diseases of women."

This book is a collection of articles contributed by 72 authors, each an authority in the field of his writing. The editors are to be congratulated on their success in persuading these representative men to contribute, for the value of a volume of this type depends upon the authority with which the many authors can speak. The wide field of interest of these contributors indicates the breadth of the field of gynecology today. In addition to many gynecologists, the authorship includes internists, obstetricians, pathologists, anatomists, general surgeons, endocrinologists, a biochemist, a hematologist, a psychiatrist, a neurologist, and a geneticist.

It has been the purpose of the editors to bring out the varied points of view. For example, the section on carcinoma of the cervix includes a chapter on, "The Relation of Intraepithelial Carcinoma to Invasive Cancer of the Cervix," a chapter on, "Cancer of the Cervix, Principles of Radiation Treatment," a chapter on, "Cancer of the Cervix, Vaginal Cone Method of X-ray Irradiation," a chapter on, "The Wertheim Operation," a chapter on "Pelvic Lymphadenectomy in the Treatment of Cervical Cancer," and a chapter on "Cancer of the Cervix in Pregnancy." As a result of presenting the subject in this manner it becomes apparent that the editors are attempting to convince the reader that the subject is a living one and that many gynecologists are searching for the answer along different paths.

In addition to good sound advice on the older clinical subjects given by seasoned gynecologists, the book contains chapters on newer and more controversial subjects such as culdoscopy, various endocrinological subjects and menstrual toxin. These subjects are presented by special workers in their respective fields and perhaps their ideas indicate unjustified enthusiasm. This statement is not to be construed as a criticism, for in these chapters lie stimuli for thought that every reader should receive. Although the volume was prepared primarily for the returning medical veteran who is interested in gynecology it can be read to great advantage by all gynecologists and obstetricians. Those gynecologists who were not in the armed forces have been so engrossed in routine teaching and practice that a refresher course such as is given in this book can be taken with profit.

R. W. TE LORRE.

THIS monograph, entitled *Ulcer of the Stomach, Duodenum and Jejunum* by Dr. Ralph C. Brown, is a book of great value for the medical student and general practitioner. The author gives a short résumé of ulcer history and a brief review of present day trends in ulcer treatment. His x-ray film contours are interesting and instructive. The

higher than that in the pulmonary artery and finally when the size and structure of the heart is such that it can adjust itself to the altered circulation. Fluoroscopy aids in the determination of the size and structure of the heart. The heart should not be enlarged. There is no fullness of the pulmonary cones and no pulsations in the lung fields. Usually there is an absence of hilar shadows. However in patients with extensive collateral circulation these shadows may become pronounced but are composed of an aggregate of fine shadows and never show expansile pulsations.

The diagnosis of a right or left aortic arch is of importance because the position of the aorta determines the side upon which the operation is performed. A right aortic arch occurs in 20 per cent of the patients with a tetralogy of Fallot. In all such cases the innominate artery lies on the left. Indeed, the innominate if present lies on the opposite side to that upon which the aorta descends and furthermore the subclavian artery is given off from the innominate artery at a better angle for anastomosis than it is from the aorta. Therefore the operation is usually best performed on the opposite side from the aortic arch.

The course of the aorta is determined by fluoroscopy or roentgenography. Often the normal aortic knob is visible on the left. The right aortic knob is often hidden by a ribbon of the superior vena cava. Delinication of the esophagus with an opaque barium mixture usually clarifies the position of the aorta. Normally the esophagus descends in the midline and is indented to the right on its left margin whereas if the aorta arches to the right and descends upon the right, it indents the right margin of the esophagus to the left and the esophagus lies to the left of the midline. Normally in the right anterior oblique position, the esophagus hugs the cardiac shadow and is slightly displaced backward by the aorta, whereas in cases of a right aortic arch the esophagus is independent of the aorta in the right anterior oblique position.

The factors influencing selection of patients are (1) the age and size of the patient, (2) the severity of the anoxemia, and (3) the height of the red blood count, hemoglobin and hematocrit.

The optimum age for the patient is between 5 and 10 years. The use of the subclavian artery for the anastomosis is a sounder and far less dangerous operation than the use of the innominate artery. The subclavian artery in an infant is always extremely small therefore operation is not indicated in infancy unless it appears that the infant is going to die.

However if the patient is in danger of dying of anoxemia, early operation is clearly indicated. Attacks of dyspnea are common and are often severe in patients between 4 and 18 months of age. Prolonged syncope is an indication for operation.

The degree of incapacity varies greatly. With an oxygen saturation of 30 per cent most children can walk only a few feet. With an oxygen saturation of from 20 to 25 per cent few can walk at all when

it is below 20 per cent there is cause for great concern.

The height of the red blood count, hemoglobin, and hematocrit is important in the selections of the patients. If the red blood cell count is between 8 and 10 million or the hematocrit between 70 and 80 mm. the patient is in great danger of cerebral thrombosis. For such children operation is indicated. Inasmuch as dehydration increases the danger of thrombosis prior to operation these children should receive from 1 1/2 to 2 quarts of liquid a day. Twelve hours of dehydration is liable to cause cerebral thrombosis therefore, great care should be used not to dehydrate the child the night before operation especially if the operation is not done early in the morning.

Results of operation are immediate improvement in the patient's color, prompt rise in oxygen saturation of the arterial blood and the gradual fall in red blood count, hemoglobin and hematocrit. The rapidity of the fall of the red blood cell count depends upon the amount of blood lost at operation. Once the anastomosis is established there is no need for the polycythemia. Although heretofore the surgeon venesection at the end of operation is a sound physiological procedure. It lessens the load placed on the lungs. The heart is not normal. There is a loud continuous murmur, but the patient looks like a normal individual. It is not yet possible to say how much we have increased the life span of the patient, but his enjoyment of life is greatly increased. There is gradual disappearance of clubbing of the extremities and a great increase in exercise tolerance. The child can measure his activity not in terms of walking a few feet but in terms of miles.

JOHN J. MALONEY, M.D.

Blalock, Alfred: The Technique of Creation of an Artificial Ductus Arteriosus in the Treatment of Pulmonic Stenosis. *J. Thorac. Surg.* 1947 10: 244.

The technique by which one may create an artificial ductus arteriosus in the treatment of pulmonic stenosis is described. The ages of the patients ranged from 2 months to 16 years. Operation was performed on 144 patients with an over all mortality rate of 22 per cent. This total includes several patients in whom the pulmonary artery was absent or was so abnormal that it could not be found at the time of operation.

An anastomosis was performed between the end of a systemic artery and the side of one of the two main pulmonary arteries in 118 patients, with 18 deaths a mortality of 15 per cent. The subclavian artery was used in 73 of these with 5 deaths a mortality of 7 per cent. The carotid artery was used in 11 cases with 1 death a mortality of 9 per cent. The innominate artery was employed in 36 patients with 12 deaths, a mortality of 33 per cent. The author has practically abandoned the use of the innominate artery in patients who are 2 years of age and older.

An end to end anastomosis was attempted in 13 patients with 6 deaths. In 5 of the fatal cases the pulmonary artery was too small for a satisfactory anastomosis. In the remaining case the condition was improved following the operation but death occurred suddenly 6 months later from an unexplained cause.

With 1 exception all of the patients in whom an anastomosis was performed and who are living are believed to have been benefited. In the exception the intima of the subclavian artery was damaged and thrombosis occurred. There has been no mediastinitis, no empyema, no severe bleeding from the anastomotic line and thus far no bacterial endarteritis.

JOHN J. MALONEY, M.D.

ESOPHAGUS AND MEDIASTINUM

Frink, Norman William: Spontaneous Rupture of the Esophagus. *J. Thorac. Surg.* 947 6 29

A case is presented in which the patient recovered following a spontaneous rupture of a previously normal esophagus.

Diagnosis and treatment are discussed.

The reason that patients with spontaneous rupture of the esophagus die so quickly is still unexplained. Unquestionably the sudden forceful onslaught of chemical and infective mediastinitis and pleuritis is the most important factor. Just what effect this produces on the adjacent sympathetic nerves and plexuses is largely conjecture. The patient may survive the first few days, if the infection is not overwhelming, only to succumb to a massive hemorrhage from the site of the rupture when he seems to be on the road to recovery.

Because the condition is so rare and so few cases have been diagnosed during life, the literature contains but few recommendations as to therapy. Williams and Boyd suggested early thoracotomy drainage. This is also suggested by Vinson. Benson and Penberthy reported a case of rupture of an esophageal ulcer into the pleural cavity which was treated by closed drainage of the empyema; the patient recovered. Eliason and Welky recommend posterior mediastinotomy. This would appear to be the procedure of choice if the infection were limited to the mediastinum. If an empyema is present, the author recommends closed intercostal drainage preferably with constant suction. This would tide the patient over his initial toxicity. When his condition had improved sufficiently and it was believed that the mediastinum was well fixed, open thoracotomy would be done.

Surgical repair of the esophagus following spontaneous rupture has been attempted but once. In this instance the patient expired 21 hours after operation. This is truly a formidable procedure to perform on a desperately ill patient, and to be successful would have to be done within a few hours after the rupture had occurred; however, this is when an accurate diagnosis is most difficult. It would seem that these early hours might better be spent in attempt-

ing to resuscitate the patient by means of sedation, oxygen, parenteral fluids, and transfusions, with surgery limited to simple drainage of the infected region.

In the light of our present knowledge of chemotherapeutics the administration of penicillin in large doses is definitely indicated. At the same time, one of the sulfonamide salts given intravenously might be a worth while adjunct to penicillin. The efficacy of these drugs, of course, depends entirely upon the bacterial flora present.

Esophagoscopy is not recommended. Observation of a swallow of barium sulfate mixture under the fluoroscopic screen would give the same diagnostic aid as esophagoscopy with none of the disadvantages of the latter.

The use of a nasal feeding tube is open to strong criticism because of the possibility of producing further injury by the passage of the tube and the irritation the tube would theoretically produce by residing over the site of rupture. Possibly these dangers are not as great as they might seem. If it is used a chest roentgenogram should be taken immediately after the tube is passed to determine its position. Vinson has reported a case in which the tube was visualized looped outside of the esophagus into the mediastinum.

Whether or not a gastrostomy or jejunostomy should be done for feeding purposes is a moot question. Again, this is a major operative procedure for a critically ill patient. Probably those patients who survive the first few days would recover without it if a fatal hemorrhage did not intervene. The patient could well be supported during the initial few days with fluids given intravenously and subcutaneously. As soon as the patient's condition permits it is recommended that a jejunostomy be performed. This would place the esophagus at rest as much as possible while at the same time it would provide a means of supplying much needed nutrition. This is much to be preferred to gastrostomy as it would obviate the danger of a reflux of food through the rent in the esophagus. In a few cases coming to autopsy it was noted that the esophageal rupture extends into the stomach. It thus seems advisable to keep the stomach, as well as the esophagus, as empty as possible.

It would be well to have compatible blood kept in readiness in a "bank" or refrigerator so that it might be administered with no delay if hemorrhage occurs. The danger of this secondary hemorrhage is greatest during the first week or two. If the blood is ready and instantly available, its use may well prevent a fatality.

If the patient recovers, he should be checked at intervals of a few weeks or months by means of barium studies of the esophagus because of the possibility of subsequent stricture formation. If a stricture did occur treatment could be started early before obstruction intervened.

With the exception of 3 cases mentioned by Graham, this is the first case of recovery following spontaneous rupture of the esophagus to be reported. If the entity of rupture of the esophagus is borne in

mind many more cases should be diagnosed before death. Undoubtedly the mortality rate will always be high but if the diagnosis can be made early enough and prompt treatment begun more and more patients should recover. JOHN J. MALONEY M.D.

Bonzi, E., and Cora, P. L.: Polypoid Tumors of the Esophagus (Sul tumori polipoidi dell'esofago) *Rivista med. Milano* 1947 33 161

In a 2 year period at the National Institute for the Treatment of Tumors in Milan 7 esophageal polypoid tumors were observed. Six of these could be examined histologically, but the remaining growth broke off and disappeared before endoscopy could be instituted. In 4 of the 6 patients the histologic diagnosis was polymorphocellular sarcoma, adenocarcinoma papillary fibroepithelioma of Malpighian cell type (precancerous stage) and nondifferentiated carcinoma, respectively. In the remaining 2 histologically studied cases the diagnosis could not be confirmed with certainty because in the first endoscopic manipulations the pedicles were so injured that the tumor broke off and fell into the stomach before more complete biopsy studies could be done. One of these was considered to be a fibroma or a fibromyoma (benign) and the other exhibited some leucoplakia and was thought to be a simple chronic pharyngitis with polypoid development.

In none of the 3 benign cases was the tumor removed and yet the patients are still alive and well after 1 year 1 year and 3 years respectively. Of the 4 malignant cases, 1 received no treatment because of the grave condition of the patient (hemorrhage, exhaustion), and the other 2 received roentgen therapy. In the case of adenocarcinoma 8,000 roentgens produced an initial improvement with regression of the tumor 2 months later however the

tumor returned with severe manifestations of dysphagia and pain which ended in death. At present all 4 patients with malignancies are dead. Nevertheless, the irradiated cases manifested an evident radiosensitivity of the tumor cells.

From their own experience—meager it is true—and a rather fragmentary review of the literature, the authors conclude that there are no constant signs either roentgenological or endoscopic which permit a certain differentiation between the benign and the malignant polyp. This differentiation will ultimately rest upon biopsy and is particularly important because of the difference in prognosis and treatment of the two conditions. For the malignant case the authors prefer roentgen therapy while they attempt removal of the benign tumor. However they concede that, even in the case of a malignant new growth the removal of the whole or a part of the intracophageal obstructing mass may afford palliative relief. Because of the necessity of respecting the thinned and stretched esophageal wall at the point of attachment of the polyp the authors believe that the deliberate though not brutal endoscopic manhandling of the pedicle with the intent of injuring it to the point where it will later give way spontaneously is justified.

Surgical intervention by the external route is to be considered only in the presence of a benign polyp of particularly voluminous character. In the external approach in the malignant case it is admitted that there is a chance by removing the entire circumference of the esophagus itself of removing the condition before it has spread through the esophageal walls however such an operation is to be attempted only in special centers with the aid of especially experienced personnel.

JOHN W. BRENNAN M.D.

An end to end anastomosis was attempted in 13 patients with 6 deaths. In 5 of the fatal cases the pulmonary artery was too small for a satisfactory anastomosis. In the remaining case the condition was improved following the operation but death occurred suddenly 6 months later from an unexplained cause.

With 1 exception all of the patients in whom an anastomosis was performed and who are living are believed to have been benefited. In the exception the intima of the subclavian artery was damaged and thrombosis occurred. There has been no mediastinitis, no empyema, no severe bleeding from the anastomotic line and thus far no bacterial endarteritis.

JONAS J. MALOFEV, M.D.

ESOPHAGUS AND MEDIASTINUM

Frink, Norman William: Spontaneous Rupture of the Esophagus. *J. Thorac. Surg.* 9:47 19 191

A case is presented in which the patient recovered following a spontaneous rupture of a previously normal esophagus.

Diagnosis and treatment are discussed.

The reason that patients with spontaneous rupture of the esophagus die so quickly is still unexplained. Unquestionably the sudden forceful onslaught of chemical and infective mediastinitis and pleuritis is the most important factor. Just what effect this produces on the adjacent sympathetic nerves and plexuses is largely conjecture. The patient may survive the first few days, if the infection is not over whelming, only to succumb to a massive hemorrhage from the site of the rupture when he seems to be on the road to recovery.

Because the condition is so rare and so few cases have been diagnosed during life, the literature contains but few recommendations as to therapy. Williams and Boyd suggested early thoracotomy drainage. This is also suggested by Vinson. Benson and Penberthy reported a case of rupture of an esophageal ulcer into the pleural cavity which was treated by closed drainage of the empyema; the patient recovered. Eliason and Welky recommend posterior mediastinotomy. This would appear to be the procedure of choice if the infection were limited to the mediastinum. If an empyema is present the author recommends closed intercostal drainage, preferably with constant suction. This would tide the patient over his initial toxicity. When his condition had improved sufficiently and it was believed that the mediastinum was well fixed, open thoracotomy would be done.

Surgical repair of the esophagus following spontaneous rupture has been attempted but once. In this instance the patient expired 2 hours after operation. This is truly a formidable procedure to perform on a desperately ill patient, and to be successful would have to be done within a few hours after the rupture had occurred; however this is when an accurate diagnosis is most difficult. It would seem that these early hours might better be spent in attempt-

ing to resuscitate the patient by means of sedation, oxygen, parenteral fluids, and transfusions, with surgery limited to simple drainage of the infected region.

In the light of our present knowledge of chemotherapy the administration of penicillin in large doses is definitely indicated. At the same time, one of the sulfonamide salts given intravenously might be a worth while adjunct to penicillin. JOHN W. BRECKENRIDGE M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Gaston, Eugene A.: Living Fascial Sutures in Inguinal Herniorrhaphy. *Arch. Surg.*, 1947 54 424.

The author presents a personal series of 201 inguinal hernias treated most proficiently by the use of living fascial sutures. His follow up statistics are carefully documented and his recurrence rate is only 1.74 per cent.

The anatomy and physiology of the inguinal region are clearly and simply reviewed, particularly in the light of the recent work of Anson and McVay. The pathologic changes in both direct and indirect inguinal hernias are discussed and their structural similarities in regard to herniorrhaphy are stressed.

A technique for the surgical repair of inguinal hernias is explicitly described in which the following points are significantly emphasized: (a) an adequate incision, (b) ample exposure and painstaking repair of the transversalis fascia, and (c) broad approximation of the internal oblique muscle to the inguinal ligament, lateral as well as medial to the internal ring, by means of a combination of silk and living fascial sutures. The fascia used is a strip of the external oblique aponeurosis as shown in Figures 1 and 2.

The operative mortality rate was 0.5 per cent: 1 death occurring in a patient with a strangulated direct hernia who had peritonitis and a pulmonary infarct.

These personal case records kept by the author were indeed conspicuous by their comprehensiveness and detail. For example the difference in the insertions of the internal oblique muscle was care-

fully noted in most cases, as was the condition of this muscle relative to age, duration of the hernia, and the wearing of a truss.

Complications are discussed and a detailed summary of results is unequivocal and to the point.

EDWARD F. LEWISON, M.D.

GASTROINTESTINAL TRACT

Maimon, S. N., Bartlett J. P., Humphreys, E. M. and Palmer W. L.: Giant Hypertrophic Gastritis. *Gastroenterology* 1947 8 397.

A review of 5765 gastroscopic examinations carried out at the University of Chicago Clinics revealed 6 cases of giant hypertrophic gastritis verified at operation. Four other cases were diagnosed on the basis of x ray and gastroscopic findings, 1 being confirmed by operation—an incidence of 0.17 per cent. The cause is unknown. The gastroscopic findings, the pathology and the histologic observations in each of the cases are discussed in detail.

From the standpoint of the clinical diagnosis, the differentiation of giant hypertrophic gastritis from carcinoma by roentgenography or by gastroscopy in the cases presented was unsatisfactory. In 2 of the 6 cases of giant hypertrophic gastritis a superimposed hyperplastic polyp formation was observed. Considerable difficulty was encountered in differentiating this condition from neoplasm. Anatomically roentgenologically and gastroscopically the resemblance of the gastric folds to the convolutions of the brain is striking and is perhaps the most salient feature.

Fig. 1 (Gaston) Fascial suture used to approximate the internal oblique muscle to the inguinal ligament superficial to the interrupted sutures. The inset shows the broad approximation thus established.

Fig. 2 (Gaston) A second fascial suture being inserted lateral to the internal inguinal ring. The inset shows complete closure of the inguinal defect after division of the spermatic cord preparatory to orchiectomy.

ing mattress sutures passing through the liver substance proximal to the line of incision in the liver. These are placed prior to the incision of the liver for the purpose of immediate control of bleeding by compression.

The author reports 3 cases. In all 3 the tumors were hepatomas, liver cell tumors of low grade malignancy. The first patient, a man of 73 years who is alive and well after 22 months, had a resection of the entire left lobe. Resection of the left lobe proved to be easier technically than resections of portions of the right lobe. In the second case that of a child 3 years of age a huge tumor of the left lobe and invading the right lobe was successfully resected but the patient died 6 months later with recurrence of the tumor. The third patient, a child 20 months of age, had a much smaller tumor of the right lobe, and had a much more favorable prognosis.

LICK PULLEN M D

Hoyne, Robert M. and Kernohan, James W.: Primary Carcinoma of the Liver; A Study of 31 Cases. *Arch. Int. M.*, 1947 79 532.

Primary carcinoma of the liver is a rare disease. Thirty-one cases have been found in 16,303 autopsies at the Mayo Clinic, an incidence of 0.19 per cent. Six of these cases had been previously reported in the literature. The disease occurs most commonly in the Orient and South Africa. A series of reports collected from the literature reveals an incidence of 0.227 per cent among the white skinned races of Europe and America and an incidence of 0.983 per cent among the Asiatic and African races. This increased tendency of the disease to afflict the latter peoples is believed to be due to the high geographic incidence of schistosomiasis and clonorchiasis among these peoples and to the chronic irritation of the liver caused by these parasitic infections.

Primary carcinoma of the liver is a disease of older persons. In most of the authors' cases the lesion occurred in the fifth, sixth and seventh decades of life. In 23 of these 31 cases the disease occurred in males the sex which is more frequently afflicted. Primary carcinomas of the liver arising from liver cells are called "hepatomas" and those arising from bile ductules are called cholangiomas. Reports of hepatomas in the literature far exceed those of cholangiomas. In 20 of the 31 cases the tumors were hepatomas and in 11 they were cholangiomas. Cirrhosis frequently is associated with primary carcinoma of the liver, and undoubtedly is an important causative factor. In 15 of the 20 hepatomas (75 per cent) cirrhosis was associated but it was present in only 2 of the 11 cases of cholangiomas (18.2 per cent).

It is still debatable whether the incidence of primary carcinoma of the liver is any greater in the presence of hemochromatosis than it is when nonpigmentary cirrhosis alone is present. There are no pathognomonic clinical or laboratory signs or symptoms in these cases, and the diagnosis is rarely made before death of the patient. The most significant symptoms and signs in the cases were emaciation

abdominal distention with ascites abdominal pain edema of the ankles, jaundice, and a palpable abdominal tumor.

Cross distinction between hepatoma and cholangioma usually is difficult, and the final diagnosis must be made histologically. The question of multicentric or unicentric origin of these tumors is still debatable most authors favor the latter view. Eleven of the 20 hepatomas were characterized by obvious invasion of the blood vessels. The early vascular involvement is thought to cause the intrahepatic metastasis so often seen in the presence of hepatoma. Tumor thrombosis of the inferior vena cava and right auricle may accompany these tumors. In 21 of the 31 cases, 67.7 per cent, extrahepatic metastasis was present. Cholangioma as a rule metastasizes earlier and more frequently than does hepatoma. The tumors under consideration grow exceedingly rapidly and the prognosis usually is hopeless. Early surgical resection of the liver offers the only chance for cure in these cases.

Baker H. L. and Caldwell D. W.: Lesions of the Ampulla of Vater. *Surgery* 1947 21 523.

The report concerns itself with 4 different lesions of the ampulla of Vater which have been observed in the past 3 years. The conditions are (1) cystic dilatation of the common bile duct (2) benign papilloma of the ampulla, (3) adenocarcinoma of the ampulla and (4) ulcer of the duodenum affecting the ampulla.

It is well to recognize that only at operation can cystic dilatation of the common bile duct be regularly differentiated from the more frequent, less hopeful malignant neoplasms. The condition appears almost entirely in childhood or young adulthood and is most frequent in females under the age of 25 years. Rolleston suggested the causes of cystic dilatation to be (a) idiopathic, that is, no obvious obstruction considered to be due to a primary inherited weakness of the wall of the duct, and (b) obstruction at the distal end of the common duct due to congenital stricture, trauma, stones or surgery and infections such as syphilis, typhoid, and those resulting from a more heterogeneous group of bacteria from the intestine. The condition is accompanied by symptoms and findings such as recurrent jaundice and occasionally paroxysmal pain.

The importance of benign papillomas of the ampulla of Vater is obvious inasmuch as their differentiation from early malignant growths is not possible except at the time of surgical exploration. The further importance of such tumors is emphasized when one realizes that 70 per cent of the also rare carcinomas of the duodenum are located at the ampulla.

Accepted by some is the belief that primary carcinomas of the region of the ampulla of Vater start as benign papillomas. This is because of the similarity of the gross and microscopic appearance of benign tumors to that of the low grade papillary carcinomas. The question has been raised as to the possibility that ulceration of the peripapillary duodenum is the precursor of such malignancies.

3. The annular type of carcinoma occurs somewhat more frequently in the left colon than in the right colon.

In the light of the current emphasis that salvation in malignant disease rests in the last analysis, with the patient and depends upon his consulting the doctor early it is as ironic as it is tragic that 18, or 22 per cent, of these patients did seek medical aid at intervals varying from 1 to 18 months prior to obstruction. Three of them were told to take purgatives 1 was given medicine 1 was treated 7 months for dysentery 1 was told he had a gastric ulcer and another was told that the symptoms were due to "womb trouble."

Four had been operated upon—2 had appendectomies 2 weeks and 15 months before entering the hospital 1 had a colectomy for "volvulus" of the cecum 3 months prior and 1 had had "release of adhesions" 18 months prior. FRANK B. QUINN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Snell, A. M.: Jaundiced Patients. *J Am M Ass* 1947 133 1175

Success in the management of jaundiced patients appears to depend on increased accuracy of diagnosis, especially in the differentiation of obstructive from hepatocellular jaundice. The value of profile hepatic functional studies, especially those concerned with urobilinogen metabolism is discussed.

The indications for surgical intervention in cases of jaundice include (1) the proved or presumed presence of stone (2) the development of jaundice after cholecystectomy (3) the presence of associated biliary fistulas, and (4) proved complete acholia. The relative contraindications for surgical treatment are discussed with reference to the signs and symptoms of serious primary or secondary hepatocellular injury.

The established principles of medical treatment include a highly nutritious diet, the maintenance of normal hemoglobin and protein levels, the use of vitamins for the correction of specific deficiencies, and the employment of lipotropic substances and liver extract.

Ferguson, L. K., and Anderson, R. K.: Amebic Liver Abscess in Service Personnel. *Gastroenterology* 1947 8 35

With the return of the armed forces who have been on duty in areas in which the incidence of amebiasis is high, the appearance of the disease and its complications may be expected to increase.

From a surgical point of view the most important complication of amebiasis is liver abscess. Many abscesses progress, without recognition, to more serious complications. Perforation through the diaphragm to involve the pleural cavity is usually a late complication and was not seen in the authors' cases. The more common complication is secondary infection of the abscess with pyogenic organisms. Frequently the acute symptoms of a pyogenic infec-

tion are the presenting complaints. In the present series, the time from the amebic colonic symptoms to those of liver abscess varied from 1 month to 1 year.

The authors have seen no extension of the amebic or infective process from aspiration or drainage in cases in which emetine and penicillin were used in the postoperative period.

A two stage transdiaphragmatic procedure is used. The abscess is located by exploring with an aspirating needle, under local anesthesia, at the site of the most acute local tenderness produced by fist percussion or deep intercostal pressure. A large, long needle should be used. When pus is found, a small amount is aspirated, enough to relieve tension in the abscess, and to serve for smear and bacteriologic study. The needle is detached from the syringe and left in place, and the rib above or below the needle is resected subperiosteally for a distance of about 2 inches. Care should be taken not to injure the underlying pleura. The wound thus produced is tightly packed with iodoform gauze, the aspiration needle is then removed and a tight dressing applied. After an interval of 3 or 4 days, the patient is returned to the operating room and, under local anesthesia, the iodoform packing is removed. The parietal and diaphragmatic pleuras are now adherent, and transdiaphragmatic drainage may be carried out without danger of infecting the pleural cavity. The exploring needle is again used to locate the abscess cavity and with this as a guide, the abscess is opened through the diaphragm. Once pus is located an aspirator is used to evacuate the contents of the cavity and the opening is enlarged sufficient to permit the introduction of one or two large rubber drainage tubes. An iodoform pack is used to control the oozes by introducing it along the tubes into the abscess cavity and in the wound.

The diagnosis is not always easy because the demonstration of ameba in the stools may be difficult, the history indefinite, and the period from dysentery to abscess considerably long.

Four case reports are included which illustrate the difficulties of diagnosis. JOSEPH GASTER, M.D.

Dockert, J. W., and Montgomery, H. G.: Resection of Primary Liver Tumors. *Surgery* 1947 455

Recent advances in our knowledge of the physiology of the liver and gradual accumulation of clinical data from reports of surgical cases have fairly well eliminated the fear of producing insufficiency by removal of large portions of this organ. The right and left branches of the hepatic artery anastomose freely so that if either main branch is divided during the course of resection, the intact branch can adequately supply the remaining portions of the liver. However extreme care must be taken to avoid damage to the main hepatic artery. Even temporary compression of the hepatic artery produces symptoms of shock and consequently this method of control of hemorrhage from the liver is unsuitable.

The method of controlling hemorrhage described by Pickrell and Clay is the use of a line of interlock

most always accompanies colic and icterus affords some basis for this statement together with the fact that various degrees of inflammation were found in all specimens which the authors examined.

Eppinger states that in certain dyskinesias extravasation of plasma at the level of the terminal common duct can cause obliteration of the duct. Icterus in effect is caused by an edematous tumor of the ampulla of Vater. This process occurs whether or not calculi are present in the duct. Since the symptoms usually regress in spite of the persistence of a stone it would appear that when no impaction is present the calculi are not the direct cause of the obstruction. The dilatation of the duct is dependent upon the degree of hypertrophy of the sphincter. Stones, when present act only indirectly by favoring the change in the musculature. Their role is secondary since dilatation frequently continues after the stone is removed.

ORVILLE F. GRIMES, M.D.

Lagerlöf, Henriki: Choledochal Denervation In Biliary Dyskinesia. *Lidski skand* 1947 95 307

Reich in 1940 suggested that the pain of biliary dyskinesia might be relieved by sectioning the intrinsic nerves of the biliary tract thereby inducing a paresis of the sphincter of Oddi with consequent decrease of pressure in the common bile duct. In one cholecystectomized patient he showed that the intracholedochal pressure was reduced from 125 millimeters of water before to 85 millimeters 10 days after operation. Injection of morphine caused a precipitate rise to 120 millimeters, but because this was not maintained for several hours he concluded that the residual pressure of 85 millimeters was the result of duodenal tonus.

In the present study 15 cases of biliary dyskinesia were investigated. All but one of the patients had previously undergone cholecystectomy and the second operation was primarily done to exclude stones in the common duct. The diagnosis of biliary dyskinesia was made on the similarity between spontaneously occurring biliary colic and pain induced by morphine. Also since theoretically the simultaneous injection of morphine and secretin should lead to spasm of the sphincter of Oddi status in the pancreatic and biliary ducts and resultant pain and elevation of the serum amylase and bilirubin a 'morphine-secretin' test was done before and after choledochal denervation.

Choledochal denervation as carried out in all 15 cases consisted of the removal of a 2 cm. section from a rather large nerve trunk which was found to arise from the celiac plexus. This nerve which has been identified in anatomical studies (Latarjet, Perman) as the 'nerf pancreatocolocholele', courses behind the portal vein to the common duct in the area of the neck of the gall bladder and from this point descends dorsally and medially to the duodenum. In all cases common duct exploration was carried out as well as section of the contiguous nerve trunk.

Following the choledochal denervation pain was relieved in 14 of the 15 patients and the rise of serum amylase and bilirubin in response to morphine and secretin was found to be lower than preoperatively. Although the relief of pain postoperatively may be due to interruption of the pain pathways and/or decrease of the tone of Oddi's sphincter, the author believes that the results of the morphine-secretin test indicate that the sphincter contracts less strongly.

The effects of choledochal denervation lasted only a few weeks to months, probably because of regeneration of the nerve fibers hence the operation is of little practical value and is not advised save in cases in which the biliary tract is explored on suspicion of choledochal stone or inflammatory changes in the remnant of the cystic duct and in which no pathologic process is found.

WAYNE CAMERON, M.D.

Koller, Oddmund: Acute Interstitial Pancreatitis Provoked by Hemolytic Streptococci In Infected Food (Fish). *Acta chir scand* 1947 95 358.

The author describes in detail 2 fatal cases of acute, interstitial nonpurulent pancreatitis due to hemolytic streptococci isolated from specimens taken at operation and at postmortem examination. Both patients were elderly men who had shared board and lodging and who developed at about the same time violent abdominal pain radiating to the back and accompanied by vomiting. Death occurred in 3 and 5 days, respectively and at autopsy the findings in both cases were remarkably similar. In both there was a slight cloudy peritoneal exudate, a gelatinous edema of the duodenum edema and hyperemia of the pancreas from which short chain hemolytic streptococci were isolated and cerebral edema.

Follow up inquiries revealed that 3 members of a household had eaten warmed-over halibut and had become ill the following day. Death occurred as described in 2 of the members, but the third person after a 24-hour bout of abdominal pain and diarrhea had recovered. Nearly 8 weeks after his illness the serum of this patient showed a high anti-streptolysin titer which denoted a recent severe streptococcal infection.

The pathologic-anatomical picture of the 2 cases described is similar to that of Zopf's pancreatitis edematosa and Elman's acute interstitial pancreatitis which is usually interpreted as an aseptic process possibly as the initial stage of acute pancreatic necrosis. The author points out that as the etiology of acute pancreatic necrosis is obscure, more careful bacteriological examinations should be carried out in cases of disease of this viscous particularly as it has been shown experimentally that bacteria may play a decisive or a contributory part in activating the pancreatic enzymes. He considers it not illogical therefore to consider chemotherapy with a view to preventing secondary infections with consequent intensification of the process and septicemia.

WAYNE CAMERON, M.D.

Most of the papillomas are of a columnar epithelial type and not of glandular formation. This is in contradistinction to the glandular type of formation of the carcinomas. The tumors are usually very small. They may be cystic or solid and consist usually of small hard white masses, often readily mistaken for an impacted calculus or a carcinoma. The most common symptoms and findings are those of painless jaundice, generalised pruritis, weight loss (due to retention of bile and loss of external pancreatic secretion) hepatomegaly fever and diarrhea.

Ampullar carcinoma is relatively rare. Adenocarcinomas of the region of the ampulla of Vater are the most common in this area. On gross examination *in situ*, these may readily be mistaken for small calculi or benign neoplasms. Therefore, they must be most closely scrutinized and biopsy made if at all possible.

Ulcer of the duodenum affecting the ampulla of Vater is a rather rare condition which may come about as the result of a primary ulcer in this region or as the result of marginal ulcers following various gastroduodenal anastomoses for intractable ulcers of the stomach or first portion of the duodenum.

The author presented 4 cases, each of a different pathologic nature but with marked similarity of symptoms and findings, such as persistent jaundice, pruritis, anorexia, weight loss, and stool color changes. Because of such similarity and the great difference in prognosis, the following conclusion is expounded.

In those patients with biliary tract obstruction producing symptoms and physical findings which cannot be readily explained by the simpler less hazardous means, the surgeon is thoroughly justified in exploring the ampulla of Vater transduodenally, and, in agreement with Brunschwig, transduodenal resection with reimplantation of the ducts with or without internal biliary drainage should be the choice for ampullar carcinomas of 1 cm. or less in diameter which appear quite circumscribed or show little gross evidence of infiltration and which do not extend into the pancreatic tissue.

LEE POLLEY M.D.

Bergolts, A. J., and Negri, A.: Disease of the Terminal Common Duct (*La maladie d'choledoque terminal*). *Rev. chir. Par.* 1947 66 65

The literature frequently makes mention of a functional alteration in the sphincter of Oddi as the cause of the persistence of symptoms following operations on the biliary tract, most often following cholecystectomy. Sphincteric spasm no doubt exists but it does not account for all the postoperative difficulties not otherwise due to such entities as residual lithiasis, pericholangitis, cicatricial stenoses, or extrinsic pathological processes. The more or less permanent nature of the symptoms, the inability to observe sphincteric spasm by cholangiography, the frequency of fever which precedes or accompanies the syndrome, and the futility of the use of biliary hypotensives all militate against a spasmodic mechanism as the primary cause.

Organic lesions in the duodenal portion of the common duct have been noted and studied micro-

scopically by the authors. The primary lesion consists in hypertrophy and hyperplasia of the muscle of Oddi. The hypertrophy assumes a concentric form and thereby infringes upon the lumen of the duct. This alteration usually is caused mechanically from irritation derived from an adjacent inflammatory process such as duodenitis or diverticulitis. The hypertrophy is always followed or accompanied by a glandular hyperplasia which can become almost adenomatous. The hyperplasia develops toward the lumen so that in certain instances the lumen is so reduced that it almost disappears from the microscopic sections.

Inflammatory infiltration along with the fibrous involvement of the muscular tissue and mucosa is likewise notable. In all except 2 of the authors' cases, the inflammation was chronic and most marked in the mucosa which suggests that the mucosal infiltration is primary and the muscular infiltration secondary. In the later phases of the inflammatory process the deposition of additional tissue by fibrosis causes thickening and induration of the duct. Much of the glandular tissue becomes encased in fibrous tissue.

The presence of tissue edema in the distal common duct was striking in the authors' cases, suggesting that the participation of the serous process perhaps completes an otherwise incomplete obstruction.

This pathologic picture is produced both by lesions of the biliary tract and by lesions of adjacent organs. The presence of calculi in the common duct does not necessarily cause complete obstruction. Unless they promote an inflammatory response or become impacted their significance as a cause of obstruction is decreased.

Duodenal disease particularly ulcer duodenitis and diverticulitis may also provoke gross alterations in the terminal bile duct. Duodenitis, irrespective of origin, by progress of the irritation up the common duct, favors thickening and inflammation of its terminal portion. Strauss mentions 29 cases of chronic biliary stasis without stones which were caused by extension of an inflammation of the duodenum into the common duct with the production of thickening and fibrosis. Diverticulitis causes obstruction in a similar manner. In 1 of the authors' cases, complete obstruction of the common duct was caused by an infected diverticulum adjacent to the ampulla of Vater.

Inflammatory diseases of the pancreas which may partially stenose the common duct by compression may also cause anatomical changes in the terminal duct by extension of the inflammation.

The authors suggest that such anatomical changes exist in many patients complaining of biliary disease with or without lithiasis. Their existence constitutes an incomplete obstruction which will allow the passage of bile unless the balance is upset by some inflammatory process. The inflammation provokes congestion and edema which reinforces the pre-existent obstruction, and the passage of bile is completely blocked. The rise in temperature which al-

REVIEWS OF NEW BOOKS

123

section on diagnosis and differential diagnosis is excellent. Dr. Brown's description of the exacting treatment of ulcer that has proved its value through the years should be especially studied. In the reviewer's experience ulcer has been treated more successfully than has any other condition met with in internal medicine. Ulcer is not a disease that can be neglected or slighted if it is to be cured. The excellent results obtained on Dr. Brown's service, and the few intractable cases requiring surgery speak well for the efficacy of his therapeutic measures. The book is concise, well organized and outlines a management of patients with ulcer that has proved its value through the years.

A. J. ATKINSON

AFTER 5 years Drs. Mazer and Israel have made available a second edition of *Menstrual Disorders and Sterility*. The new edition is the same attractively printed and readable volume as its predecessor with revisions and additions to its pre material from which the authors draw liberally to substantiate their text.

The treatment of the subject closely follows that of the first edition. An enlarged section on the physiology of the ovary and pituitary is followed by a group of chapters on amenorrhea, uterine bleeding and sterility. A discussion of artificial insemination has been added and in the artificial insemination duct many excellent illustrations of tubular pathology. The appendix now contains a more complete summary of most of the available commercial endocrine preparations.

The chapter bibliographies in general will serve as comprehensive reference lists on almost every facet of the subject matter discussed. The omission of certain recent work of significance is thus thrown into rather sharp focus. One finds no mention of a possible luteotrophic factor in the section on physiology and some investigators will not be content in accord with the authors' statement in summarizing the therapy for dysfunctional flow that "Since neither estrogen nor progesterin is capable of enhancing the pituitary-ovarian mechanism, it is difficult to rationalize such treatment." Drs. Mazer and Israel report considerable success in treating anovular menstruation with combined gonadotrophic. Their reference to the work of some of the original proponents of this therapy, however, does not include more recent reports by the same authors in which the success from such treatment is seriously questioned.

The problem of sterility is handled in the last nine chapters. Empiric use of low dosage irradiation of pituitary and gonads was followed by pregnancy in 65 out of 78 barren women with amenorrhea or oligomenorrhea. Certainly success such as this, reported by the authors in an analysis of 695 cases of sterility deserves the attention of other workers in this field.

The family physician may find that the wealth of detail presented in this volume is somewhat confusing in the clinical management of his cases and he may regret the lack of a more critical assessment by the authors of much of the work by others quoted. This book is of more particular interest to the specialist whose experience may justify discrimination in accepting all of the therapeutic principles and procedures mentioned.

SOMER H. STUBBS

THE book *Adolescent Sterility* is an interesting and well written monograph which attempts to answer the question: What, if any interval of time normally elapses between the appearance of the first menstruation, the menarche, and the ability to conceive and carry a fetus to term? The evidence that a period of adolescent sterility exists in most mammals and that the onset of fertility is not synchronous with reproductive maturity has been presented in a very readable manner. This text will be of most interest to investigators of problems of human fertility, anthropologists, and endocrinologists.

JOHN W. HUFFMAN

THE highly specialized book, *A Manual of Tomography* by Weinreb, will serve well as a reference for those interested in body section radiography. Even those radiologists who have had considerable experience in the method will find it useful. The theory and the technical aspect of the method are presented briefly in Chapters I and VII. The section on theory is inadequate without supplementary reading from the references in order to obtain a full understanding of the method as the section on technique will serve well as a guide for the technician.

The chapters on the clinical application of the method present rather fully the findings in most of the conditions in which tomography is a useful aid in diagnosis. The superiority of the method in the demonstration or appraisal of many lesions in the roentgenogram with the comparison of the body section gram of the same region.

The text is elaborately illustrated with 391 reproductions of x-ray films on its 567 pages. These reproductions are unfortunately have been printed in the positive (black and white reversed from the original) and for this reason frequently fail to bring out details which are discussed in the text and which were evidently present in the original roentgenographic film. A bibliography of some 69 references is included and the index is adequate.

The book has been well printed on a good quality of paper but the binding is still of war time quality.

ADOLESCENT STERILITY. By M. F. Ashley M.D. Springfield, Illinois. Charles C. Thomas Publishers, 246 M. R. C. S. (Eng.). L. R. C. P. (Lond.). F. F. R. (Lond.). D. N. R. E. (Canada). London H. K. Lewis & Co. Ltd., 1946.

DIAGNOSIS AND TREATMENT OF MENSTRUAL DISORDERS AND STERILITY. By Charles Mazer, M.D. and S. Leon Israel, M.D. New York London Paul B. Hoeber Inc. 1946

reactions. However glass tubing and stainless steel tubing left in the abdomen for 2 weeks produced no adhesions. Large open glass tubes (lamp chimney drains) anchored with stainless steel wire sutures over intestinal suture lines as a protection against leakage or necrosis of the bowel showed no adhesions at the end of 4 days.

The author discusses the methods and advantages of stage drainage of the abdomen using fine stainless steel wire sutures and a large caliber glass or other tube. However he believes that the most effective method of abdominal drainage, when there is intraperitoneal exudation leakage, or contamination is by means of a sump drain. The drain consists of a perforated tube made of glass or stainless steel in which is placed a second aspirating tube which is connected by rubber tubing with a water spigot aspirator or an electric pump.

Sump drainage of the abdomen is used with great success by the author in cases of intraperitoneal leakage from a perforated appendix with diffuse purulent peritonitis in most types of biliary surgery in large bowel resections for carcinomas, and in cases of ulcerative colitis requiring major surgery.

The use of drains for preoperative and postoperative diagnosis for the arrest of initial and recurrent hemorrhage and for the early detection of ileus and other conditions is described. The use of jejunostomy in gastric surgery is discussed and various tubular enterostomy procedures are suggested as a substitute for a formal preoperative colostomy as a decompressive measure. Abdominal aspiration drainage by means of a sump drain as shown by the author is a surgical step forward and should find an ever widening field of usefulness. **EDWARD F. LEWISON, M.D.**

Sanders, G. B., and Hodge, L. G. : Surgical Management of Gunshot Wounds of the Pelvic Viscera and Their Late Complications. *Ann. Surg.* 1947 125 399.

Because of the close association of viscera and organs of several systems within the pelvis gunshot injuries of this region are among the most severe of war injuries. The pelvic fracture itself is relatively insignificant compared to the lethal potency of injury to its contents.

The primary surgical management of these injuries guided by the principles of prompt recognition, early repair, efficient diversion of urinary and fecal currents, when necessary, and adequate drainage at all times, is of paramount importance not only for the saving of life, but for the prevention of distressing complications later.

Deviation from fundamental surgical principles in early surgical care of gunshot injuries to the pelvis and its viscera results in increased mortality and morbidity and in the necessity for further elaborate surgery involving the sacrifice of tissues and organs, with added risk to the patient.

Surgeons charged with the primary care of these injuries should be alert to the possibilities of concealed extraperitoneal damage to the bladder, recto-sigmoid, and ureters. Injuries to the ureters are most often unrecognized at the time of primary operation when an unparalleled opportunity exists for the preservation of the associated kidney.

Proximal colostomies should divert and defunction, as well as decompress. Cecostomy is not an efficient diverting or defunctioning procedure.

The proper location of a proximal colostomy should take into consideration the likelihood of further reconstructive surgery upon the distal bowel. In wounds of the pelvic colon, especially, it may be wiser to place the colostomy no lower than the transverse colon and to perform a complementary transverse colostomy along with exteriorization of a damaged pelvic colon.

Persistent fecal and urinary fecal fistulas, particularly those traversing bone, require a direct attack for permanent closure, which is most satisfactorily done transperitoneally upon a bowel defunctioned by an efficient proximal colostomy. Following efficient fecal diversion, spontaneous closure of urinary fecal communications often occurs, provided urinary decompression or drainage is maintained and infection of the urinary tract is kept at a minimum. Reopening of such an apparently closed urinary fecal communication commonly follows restoration of the fecal current, indicating that direct attack on the fistula is necessary for permanent cure in most cases.

The histories of 5 illustrative cases are presented
JOSEPH GASTER, M.D.

Morhardt, P. L.: A New Syndrome; Congenital Cystic Pancreatitis and the Rh Factor (Un nouveau syndrome: la pancréatite kystique congénitale et le facteur rhésus). *Presse méd.*, 1947 55 243

The author reviews the syndrome of congenital cystic pancreatitis and notes the case of an infant with this disease who had a brother born subequently with erythroblastosis and lterus.

It is possible that a precipitin elaborated by the mother in the amniotic fluid is swallowed by the fetus and reacts with the fixed antigens of the bronchial glands, the pancreas, and the bowel, to which the amniotic fluid has free access during fetal life.

In the opinion of the author this problem is of exceptional therapeutic interest and merits further investigation.

MISCELLANEOUS

Farris, Edward M. and Douglas, Russell V.: Abdominal Actinomycosis. *Arch. Surg.* 1947 54 434.

A brief résumé of the clinical manifestations and therapy of abdominal actinomycosis is presented.

Five cases of abdominal actinomycosis treated at the Grady Hospital Atlanta, Georgia, are reported. Apparent cures have resulted in all 5 cases.

The authors have used penicillin in all their cases in conjunction with sulfadiazine therapy. The value of chemotherapy in the treatment of abdominal actinomycosis is supported by the fact that after its prolonged use the numerous microscopic sections and repeated cultures of the surgically excised tissue showed no evidence of actinomycotic infection in 4 of the 5 cases reported here.

However surgical treatment is of the utmost importance in the treatment of abdominal actinomycosis. Surgical drainage of all abscesses and excision of diseased tissue, insofar as can be achieved are essential in the treatment of this disease.

Charles Barox, M.D.

Sweetser, T. H.: Surgery of Retroperitoneal Tumors. *J. Urol.*, Balt., 1947 57 65.

Three factors are especially important in the surgical approach to any malignant tumor (1) it must allow exposure and division of the veins and lymphatics before any tumor cells can be squeezed into them by operative manipulation (2) it must give the best possible exposure to reduce the risk by allowing better hemostasis and more accurate dissection and (3) it must do the least possible damage to the surrounding structures. The latter is less important than the first two.

Most renal and other retroperitoneal tumors have been approached by either the lumbar extraperitoneal route, or by a transperitoneal route. The lumbar incisions described heretofore are unsound for removal of malignant tumors because they require manipulation of the tumor before the blood vessels and lymphatics are divided moreover these incisions give poor exposure unless important nerve

trunks are divided. The transperitoneal incisions allow division of the renal pedicle before manipulation of the tumor but are definitely more dangerous due to peritoneal exposure.

The author advocates an incision which has the advantages and relative safety of the lumbar route, and gives even better exposure than does the transperitoneal approach. The patient is placed on his side with the kidney rest up and the usual oblique lumbar incision between the eleventh and twelfth dorsal nerve trunks is made. If the diagnosis of malignancy is confirmed the incision is extended anteriorly across the rectus muscle to a point about halfway between the navel and the symphysis pubis, and is thence extended upward as a paramedian incision to the xiphoid. All layers of muscle and fascia down to the peritoneum are included. The large triangular flap is lifted laterally and upward over the retracted rib margin. With the use of the extra peritoneal layer of fat as a line of cleavage, the peritoneum is pushed aside unopened. After removal of the tumor the wound is closed with interrupted sutures of No. 1 chromicized catgut, including all muscle and fascial layers en masse, placed before and tied after lowering the kidney rest and straightening the table. A continuous suture is placed in the external oblique fascia, and the skin is closed with clips. A Penrose drain is extended from the renal space posteriorly.

The author states that these wounds heal solidly per primum most of his patients were out of the hospital on the thirteenth day. He states that surgery for any mass in the kidney should be undertaken with the possibility of malignancy in mind, and with adequate preparation and draping of the field. The incision described preserves the nerve supply to all the abdominal muscles, and the exposure is better than with any other kind of incision.

Joseph E. Maurer, M.D.

Babcock, W. Wayne: Newer Methods of Abdominal Drainage. *Arch. Surg.* 1947 54: 365

The author briefly mentions the historical aspects of abdominal drainage. At one time surgeons, fearing to leave ligatures within the abdominal cavity left the ends hanging from the wounds.

Investigations which began with local tissue reaction to wired sutures and ligatures, inevitably led to studies of the reaction of foreign bodies to drains. The author and his surgical residents found that catgut sutures exposed on the peritoneal surface were soon covered by dense adhesions. Silk and cotton sutures formed adhesions but to a lesser degree while stainless steel wire sutures formed no adhesions.

In applying these observations to abdominal drains, it was evident that in some cases it was desirable to produce early adhesions to localize the drained area, while in other cases adhesions prevented the drainage of outlying septic areas, and were harmful. Gauze drains were surrounded by adhesions in from one-half hour to 2 hours. Rubber tubes and plastic drains produced similar fibroplastic

carried out in the aged. The established mortality rates for these age groups in relation to life expectancy are discussed.

The case records of 313 women 60 to 87 years of age were studied. These patients were on the gynecologic services of Cook County (196) Michael Reese (76), and Mt. Sinai Hospitals (41) in Chicago.

The mortality rate in old people treated surgically is higher than that in young people. Since the risk is greater in old people each patient must be studied individually. The details of proper preoperative precautions, the selection of anesthesia (especially local), meticulous operative procedures, and of proper post-operative care are presented. The author concludes that gynecologic surgery may be performed in old women (past 60 years) under urgent imperative or elective conditions if these precautions are observed.

The higher mortality rate in older people (4.5 per cent in the series studied and all occurring at Cook County Hospital) was due to sepsis, shock, embolism, pneumonic infections, uremia, cardiac failure but also to the higher incidence of malignancies. With chemotherapy and blood transfusions the most common operative complication may be combated. Hypertension without marked cardiac damage is no great hazard. It may be improved by overcoming the partial ureteral obstruction and its resultant effect on the kidneys in the correction of pelvic hernia with the prolapsing uterus.

The author observes that the relief experienced by an old woman with proctitis with good life expectancy more than balances the risk involved in the surgical care.

JOHN R. WOLFF, M.D.

Judd, G. E.: Preservation of the Upper Pelvic Floor and Bladder Support in Total Hysterectomy. *West. J. Surg.* 1947 55 209.

In the author's method of hysterectomy the abdomen is entered by a lower midline incision. The uterus is separated from the round and broad ligaments or if the adnexa are to be removed from the infundibulopelvic ligaments. The bladder flap of the peritoneum is dissected from the anterior surface of the uterus and the cervix. The uterine arteries are ligated immediately outside of the lateral aspect of the uterus, preferably at a point above the origin of the main cervical branch of the artery.

The uterine fascia which can be clearly identified is dissected from the anterior surface of the cervix. Both sharp and blunt dissections are required which should be continued downward to the anterior fornix of the vagina. By the described procedure the bladder and the ureters become easily movable thus the danger of injury to these organs is greatly diminished. At the same time, as Richardson pointed out, a less vascular area will be encountered.

Subsequently, the cardinal ligaments are clamped by placing Kocher forceps inside of the uterine fascia, closely parallel to the cervix. By adjusting the clamps within the cuff of the uterine fascia injury to the ureter can be prevented as interference with this structure becomes virtually impossible.

The cardinal ligaments are severed from the cervix, down to the lateral fornices of the vagina. Upon separation of the cardinal ligaments from the cervix it is advisable to preserve a small amount of cervical tissue to be used for suturing later on. The uterosacral ligaments are clamped and cut, and the intervening peritoneum is incised. The posterior part of the vagina becomes accessible and is entered through Douglas pouch. The cervix is severed from the vagina under direct vision with either knife or scissors. The cardinal ligaments are sutured to the lateral aspect of the vagina by figure 8 stitches. By placing the suture in the base of the cardinal ligament, lateral retraction can be prevented. In this manner the top of the vagina is incorporated into the supporting structures which previously served to sustain the cervix as well as the vagina. The top of the vagina is closed with interrupted or continuous sutures. In order to re-establish an adequate support for the vagina the cardinal ligaments are approximated in the midline and sutured to the top of the closed vagina. Thus after the cervix, which is the focal point of the endopelvic fascia, has been removed the structures which had previously supported the cervix as well as the top of the vagina are again brought into contact and united. The sutures used in ligating the cardinal ligaments are then tied together for what little additional support they can give in uniting the cardinal ligaments.

The uterine fascia together with the mobilized bladder which in the beginning of the operation had been dissected from the cervix, is now carried over the united cardinal ligaments and sutured to the uterosacral ligaments and to the posterior portion of the united cardinal ligaments as well as to the rectovaginal septum or the postcervical endopelvic fascia. Thus the main ligamentous structures of the upper pelvic floor which preoperatively were connected through the cervix laterally as well as anteroposteriorly are now brought into immediate contact.

Finally the entire operative area is covered with peritoneum by using the bladder flap.

DANIEL G. MORTON, M.D.

Reis, R. A., and DeCosta, E. J.: Stress Incontinence in the Female. *Am. J. Obs.* 1947 53 776.

The authors' study is a consideration of the various factors concerned with the involuntary escape of urine through the intact urethra. Incontinence associated with obvious etiologic factors such as fistulas, nerve lesions and congenital anomalies are not considered.

Complete incontinence is rarely encountered but partial incontinence brought on by sneezing, coughing or straining is all too common. It is to this type of incontinence that the word stress is applied.

The authors describe the anatomy of the female bladder, urethra, and associated structures and discuss the physiology of micturition. The etiology of incontinence is presented, the authors finding obstetric injury to the urethra and supporting structures the commonest cause of stress incontinence.

GYNECOLOGY

ADNEXAL AND PERIUTERINE CONDITIONS

Campbell, J. V., and Kingman, D.: Primary Ovarian Malignancy. *West. J. Surg.* 1947 55 263

Sixty-eight cases of primary ovarian cancer showing definite histological evidence of malignancy are analyzed. Fifty three of the tumors were cystic carcinomas, chiefly cystadenocarcinoma, 11 were solid carcinomas, and 5 were malignant functional tumors. In this series the 5 year salvage was 8 per cent for cystic tumors, 30 per cent for solid tumors, and 100 per cent for functional tumors. The prognosis was worse if metastases, ascites, or bilateral tumors were present. The histological grading of these tumors was believed to be an aid in prognosis.

MISCELLANEOUS

Holmstrom, E. G., and McLennan, C. E.: Menorrhagia Associated with Irregular Shedding of the Endometrium. *Am. J. Obst.* 1947 53 727

The authors employ the phrase "irregular shedding of the endometrium" to indicate a specific type of functional uterine bleeding, a clinical and pathologic syndrome characterized by a typical pathologic picture the outstanding feature of which is prolongation of shedding of the endometrium which has undergone progesterone stimulation. In addition, there is often an increase in the amount of bleeding. The diagnosis is suggested by the typical clinical history of regularly recurring menorrhagia, and may be substantiated by recovering the secretory endometrium by curettage during the course of prolonged bleeding, but well beyond the time when endometrial regeneration normally would have occurred.

The shedding of secretory tissue ordinarily is completed within from 48 to 72 hours after the onset of bleeding. Regeneration of a new surface occurs rapidly thereafter and by the fourth or fifth day of the cycle one almost routinely observes new proliferative endometrium. One should not expect to find on the fifth day of menstruation comparatively large areas of secretory glands belonging to the previous cycle. This finding, coupled with a characteristic clinical history of menorrhagia, has been the authors' criterion for the diagnosis of irregular shedding of endometrium.

During a period of 3 years, uterine curettage was done on 243 patients in the Salt Lake County General Hospital, Salt Lake City, Utah. A pathologic diagnosis of irregular shedding of the endometrium was made in 22 of these. To demonstrate the nature of the problem, 3 cases are reported in detail and microscopic sections from 5 additional cases are shown. Typical microscopic findings are described in detail.

With regard to the etiology a number of lesions in the uterus and endometrium may be concerned. The

presence of submucous myomas or endometrial polyps may interfere with the normal shedding process postabortal subinvolution of the endometrium may be associated the simultaneous occurrence of adenomyosis and irregular shedding may be indicative of a common etiology. The authors find that there still remain a large number of cases in which the etiology is obscure, and their study is concerned particularly with this group of cases.

An attempt has been made to show a hormonal basis for the condition. The authors report the results of their experiments in 4 cases in which prolonged progesterone administration was carried out. Although the results have not been consistent enough to draw any conclusions, the investigation is being continued. It has been found that the microscopic picture characteristic of the disease can be produced in the endometrium of the normal female by the injection of progesterone during the bleeding phase of the cycle.

Campbell, R. E.: The Treatment of Pelvic Tuberculosis in the Female by Radiation Therapy Based upon Experimental Evidence in the Animal and Clinical Results in the Human Being. *Am. J. Obst.* 1947 53:405

The treatment of pelvic tuberculosis in women has been subjected to considerable controversy. The author considers the radiologic aspects of therapy in this disease relative to experiments in the animal and clinical investigations in the human being.

It was decided to produce pelvic tuberculosis experimentally in the female dog and subject the animal to roentgen ray therapy in order to observe the effect. A strain of attenuated bovine tubercle bacilli which tended to produce localized nonprogressive lesions, was selected as being suitable for this research. Twenty dogs in which the tuberculous process was limited to the pelvis were used and 9 of the dogs were studied over a 2 year period.

Analysis of the results showed that roentgen ray therapy was beneficial in pelvic tuberculosis, as there was a tendency to limit the disease to the pelvis, a direct effect upon the absorption of the exudate, and reduction of the secondary inflammation. These results led the author and his associates to believe that, contrary to the previous condemnation of the use of x-ray in the treatment of pelvic tuberculosis in the female, its use should be reconsidered. Selected case reports are presented.

Lash, A. F.: Surgical Geriatric Gynecology. *Am. J. Obst.* 1947 53 766.

The author reviews the results of previous studies of gynecologic surgery in the aged, analyzes a statistical study of a fairly large series of patients, and attempts to further evaluate the advantages, and the conditions under which gynecologic surgery may be

PREGNANCY AND ITS COMPLICATIONS

The present series of 436 cases of ectopic pregnancy was gathered from the Clinica Ostetrica e Ginecologica of the University of Rome over a period of 8 years. All of the cases were carefully studied as to their past and family history, symptomatology, pathology and clinical course. Although age, social condition, the time elapsing since the beginning of sexual life, and parity of the husband and wife appeared to be predisposing factors to the ectopic condition a constitutional factor and the inflammatory changes were found to be the most common factors.

Clinical eclampsia is always preceded by the pre-eclamptic state of which albuminuria is the earliest symptom. A survey of all the concepts and observations leads to the conclusion that eclampsia is a renal syndrome, which may be referred to as uteroplacental apoplexy. The authors seek to determine whether the various symptoms of eclampsia can be dissociated from one another or whether they are simply all manifestations of a single etiology.

Does monosymptomatic albuminuria represent a pathological or clinical entity? It does not attest to disease any more than does orthostatic albuminuria appears to be solely a functional trouble of cylindruria, persistence of normal distal renal permeability and reversibility after gestation argue for a purely functional entity.

e of the nervous system, particularly the sympathetic system, in renal pathology has long been proved clinically and by animal experiments. When in functional conditions the role of the sympathetic system is significant. The character of the albuminuria, its evolution, and its habitual reversal all plead in favor of an initial functional glomerular disease. Identical with that of experimental albuminuria in the latter cases there is no pre-existing disease. This concept of gravid albuminuria substantiates the notion of a functional renal trouble of unknown origin for the notion of a renal parenchymal disease. It is by the sympathetic route that the excitation attains its receptive organ. Cannot one admit that gravid albuminuria is a functional derangement of the sympathetic nervous system?

The various symptoms of eclampsia are examined in the light of this concept. The oliguria is observed in short duration and appears to be due more to a reflex mechanism than the anuria observed in cases of acute or infectious nephritis. As to edema (absent by definition in monosymptomatic albuminuria) it exists independently of all renal manifestations and appears suddenly; its location in the body is often unusual and is not in keeping with the concept of chloride retention secondary to impaired renal permeability—which points to a functional overactivity of the posterior lobe of the pituitary gland. The role of the nervous system in hypertension has been proved by the Goldblatt experiments. Azotemia has been observed in animals on prolonged sympathetic excitation and clinically in cases of cerebral hemorrhage; both observations attesting to a functional

Operations devised to correct stress incontinence are evaluated. All these procedures have in common the tightening of the fascial planes which surround the urethra, together with reduction of the urethral lumen.

The paraurethral operation described by Berkow is presented in detail. The procedure involves an encircling incision around the external urinary meatus with subsequent paraurethral dissection toward the bladder until the urethra has been freed sufficiently to allow the dissected urinary meatus to be just under the clitoris without tension. The urethra is now anchored just below the clitoris by three interrupted mattress sutures, using chromic catgut No. 00. This upward placement of the urethra brings into view the pubococcygeus muscles which are now

united in the midline beneath the urethra by two to four interrupted sutures. The bulbocavernosus muscles are then united in the midline, thus completing the second layer of sutured muscles which hold the urethra upward.

The authors present a series of 33 patients suffering from stress incontinence, in whom the procedure was carried out. It was completely successful in 31 patients, the 2 failures occurring in women in whom the etiology of the stress incontinence was not obstetric. Patients were followed for periods ranging from 5 to 54 months postoperatively.

In conclusion the authors state that paraurethral fixation is a most satisfactory operation for the relief of stress incontinence following obstetric injury.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Fumarola, A.: Survey of 436 Cases of Ectopic Pregnancy (Considerazioni clinico-statistiche sopra 436 casi di gravidanza ectopica) *Ginecologia*, Tor 1947 13 49.

The present series of 436 cases of ectopic pregnancy was gathered from the Clinica Ostetrica e Ginecologica of the University of Rome over a period of 8 years. All of the cases were carefully studied as to their past and family history, symptomatology, pathology and clinical course. Although age, social condition, the time elapsing since the beginning of sexual life, and parity of the husband and wife appeared to be predisposing factors to the ectopic condition, a constitutional factor and the presence of inflammatory changes were found to be the principal causes. The former was commonly manifested by irregularity of the menarche or subsequent menses, or a defective previous pregnancy. To these two causes were added minor ones, such as previous gynecological intervention, the presence of structural changes (cysts or fibromas), acute or chronic enteritis, appendicitis, or peritonitis.

Review of these 436 cases indicated that prophylaxis of the causes presented could well be instituted

EDITH B. FARNSWORTH M.D.

Rivière, M., Saric, R. and NAVARRANNE, P.: Albuminurias of Gestation. New Physiopathological and Pathogenic Concepts (Les albuminuries de la gestation nouvelles conceptions physiopathologiques et pathogéniques) *Gyn. obs. Par* 1946 45 458.

Under the term albuminurias of pregnancy are included those which occur essentially because of the state of pregnancy and not from any coexistent condition such as nephritis. What the authors refer to as monosymptomatic albuminuria lasts throughout pregnancy, regresses thereafter and is often associated with symptoms of pre-eclamptic toxemia. The association of eclampsia and uteroplacental apoplexy and albuminuria is analyzed.

Monosymptomatic albuminuria occurs in from 30 to 80 per cent of all pregnancies according to various authorities. It appears most often in primiparas. It is detected most often in the last trimester of gestation. The amount of albumin in the urine varies from a trace to several grams. There is no oliguria with this type of albuminuria, the physical properties of the urine are not modified, and sediment is minimal. Infectious causes for the albuminuria have been ruled out. There may be no clinical manifestations coexistent with the albuminuria. The evolution of this type of albuminuria is variable, even without treatment it tends to stabilize itself without accident to mother or fetus. Generally it tends to increase gradually during pregnancy and disappear after parturition; it appears in subsequent pregnancies.

In the study of pre-eclamptic toxemia, albuminuria generally represents the initial symptom followed by hypertension, edema, oliguria, gastric upsets, headache, and visual disturbances. While under treatment, the subjective symptoms of pre-eclampsia disappear, albuminuria persists. Death of the fetus modifies the pre-eclamptic state in many ways but it does not modify the albuminuria.

Clinical eclampsia is always preceded by the pre-eclamptic state of which albuminuria is the earliest symptom. A survey of all the concepts and observations leads to the conclusion that eclampsia is a renal syndrome which may be referred to as uteroplacental apoplexy. The authors seek to determine whether the various symptoms of eclampsia can be dissociated from one another or whether they are simply all manifestations of a single etiology.

Does monosymptomatic albuminuria represent a pathological or clinical entity? It does not attest to kidney disease any more than does orthostatic albuminuria. It appears to be solely a functional trouble. The rarity of cylindruria, persistence of normal diuresis, normal renal permeability and reversibility of signs after gestation argue for a purely functional derangement.

The role of the nervous system, particularly the sympathetic system in renal pathology has long been known, proved clinically and by animal experimentation. Even in functional conditions the role of the nervous system is significant. The character of the albuminuria, its evolution, and its habitual reversibility all plead in favor of an initial functional glomerular cause identical with that of experimental albuminurias. In the latter cases there is no pre-existing nephritis. This concept of gravid albuminuria substitutes the notion of a functional renal trouble of nervous origin for the notion of a renal parenchymal cause. It is by the sympathetic route that the excitation attains its receptive organ. Cannot one admit then that gravid albuminuria is a functional derangement of the sympathetic nervous system?

The various symptoms of eclampsia are examined in the light of this concept. The oliguria observed is of short duration and appears to be due more to a reflex mechanism than the anuria observed in cases of toxic or infectious nephritis. As to edema (absent by definition in monosymptomatic albuminuria) it exists independently of all renal manifestations and appears suddenly; its location in the body is often unusual and is not in keeping with the concept of chloride retention secondary to impaired renal permeability—which points to a functional overactivity of the posterior lobe of the pituitary gland. The role of the nervous system in hypertension has been proved by the Goldblatt experiments. Azotemia has been observed in animals on prolonged sympathetic excitation and clinically in cases of cerebral hemorrhage, both observations attesting to a functional

Operations devised to correct stress incontinence are evaluated. All these procedures have in common the tightening of the fascial planes which surround the urethra, together with reduction of the urethral lumen.

The paraurethral operation described by Berkow is presented in detail. The procedure involves an encircling incision around the external urinary meatus with subsequent paraurethral dissection toward the bladder until the urethra has been freed sufficiently to allow the dissected urinary meatus to lie just under the clitoris without tension. The urethra is now anchored just below the clitoris by three interrupted mattress sutures, using chromic catgut No 00. This upward placement of the urethra brings into view the pubococcygeus muscles which are now

united in the midline beneath the urethra by two to four interrupted sutures. The bulbocavernosus muscles are then united in the midline, thus completing the second layer of sutured muscles which hold the urethra upward.

The authors present a series of 33 patients suffering from stress incontinence, in whom the procedure was carried out. It was completely successful in 31 patients, the 2 failures occurring in women in whom the etiology of the stress incontinence was not obstetric. Patients were followed for periods ranging from 5 to 54 months postoperatively.

In conclusion the authors state that paraurethral fixation is a most satisfactory operation for the relief of stress incontinence following obstetric injury.

JOSEPH R. W. LEE, M.D.

origin. Retinopathy and neuropathy are two peripheral manifestations of angospasm a functional state. Convulsive seizures which may or may not be preceded by albuminuria and hypertension originate from a diencephalic center. In fact all of the symptoms of eclampsia seem to have their origin in the region of the hypothalamus.

The albuminuria of gestation and all its related symptoms seen in eclampsia can be ascribed to a functional derangement of the diencephalic and pituitary sympathetic centers, which are anatomically and functionally a unit. Gestation seems to set off the hypophysial infundibular mechanisms which appear in regular chronological order.

Estrogenic studies of diabetic pregnant women reveal that in all cases in which toxemia was present there was an abnormal level of estrogens and an elevation of gonadotropin, this elevation preceding by several weeks the appearance of the pathological phenomena.

Gestation is not the only condition which gives rise to modified hormonal levels in the maternal or gamism. There is no hormone specific to pregnancy and many changes that occur in pregnancy have their counterpart in the normal menstrual cycle.

It is not unreasonable to think that the albuminuria of pregnancy is no more than a peripheral manifestation of a general process of which the physiopathological mechanisms have their origin in the diencephalon and their course through the sympathetic nervous system, under endocrine regulation.

PHILIP B. CRANE, M.D.

Ellis, J. T., Windham, S. W., Jr., McFatter, T. K., and Lattolais, S. G. Spontaneous Rupture of the Uterus. *South. Surgeon* 947 13 70.

The authors report, in detail, 3 cases of spontaneous rupture of the pregnant uterus. One patient was a primigravida of 4½ months gestation, the other a 37 year old multigravida at term. In the case of the primigravida, the condition is believed to be unusual in that sepsis following rupture of the uterus had resulted in a fistula of the abdominal wall through which a fetal hand was protruding. The multigravida was delivered of a living child by cesarean section though the fetus had been extruded completely into the peritoneum.

In America rupture of the uterus occurs less frequently than in Europe because there is less pelvic distortion due to rickets and osteomalacia and more medical supervision in obstetrics. The incidence of this condition, as reported in large obstetrical centers, ranges from 1 in 95 to 1 in 4,000 deliveries. It occurs only rarely before the onset of labor. Balach, in 1903, collected 78 such cases from the literature. Since that time the list has grown very gradually but the condition is still rare. The etiological factors include previous cesarean section, especially of the classical type, previous myomectomies improper and energetic curettements and previous pelvic infection. This last factor is considered one of the important predisposing causes to uterine rupture.

Microscopic study of these uteri show increased fibrous tissue in the uterine wall.

Rupture of the uterus before the onset of labor usually occurs in the fundus, whereas ruptures occurring during labor are more often in the lower uterine segment.

Practically all cases of spontaneous rupture of the uterus are in multiparas with an average of 4 to 6 siblings in the various groups reported.

The signs and symptoms in the order of frequency are bleeding severe pain, abdominal tenderness, cessation of labor shock, pallor change in position of the fetus, syncope blood in the urine and distention. Two of these symptoms are emphasized cessation of labor and blood in the urine. These symptoms plus abdominal tenderness should always be treated as rupture of the uterus.

The treatment of choice is laparotomy. Only by this means can a normal infant be delivered and the hemorrhage stopped and the uterus repaired or removed. Shock must be treated with sufficient blood or plasma. Infection must be combated by drainage sulfadiazine and penicillin.

The maternal mortality varies in the series reported from 50 to 100 per cent. The fetal mortality is about 90 per cent. In the authors cases, both mothers died however one of the infants lived.

HARRY FIELDS, M.D.

Russell, P. B., Jr.: Abortions Treated Conservatively; a 12 Year Study Covering 3,739 Cases. *South. M. J.* 1947 40: 3 4.

The author's cases of abortion are divided into three groups based upon the years in which they occurred. Further classification was based upon the clinical picture and was as follows.

- 1 Spontaneous, with onset from no apparent cause.
- 2 Criminal, with a history of an aborted patient or instrumentation.
- 3 Complete, with a history of pregnancy and the passage of products of conception. Little or no uterine activity.
- 4 Incomplete, with a definite history of pregnancy and the passage of some part of the products of conception.
- 5 Febrile with a temperature of 100.4 F or more on 2 or more days after the first 24 hours, and with or without active signs of infection. (These patients should be isolated.) About one-fourth of the total will be in this group.
- 6 Afebrile with no fever or active signs of infection on admission or during the convalescent period. About 75 per cent of the cases were in this group.
- 7 Septic, with a history of abortion and the lapse of some time before admission of the patient to the hospital.

A vaginal examination should be limited to the introduction of the speculum for smears. In general, the treatment is as outlined below.

- 1 The vulva should be prepared with sterile soap and shaved. A perineal douche of 1 to 1000 mercuric

THE seventh volume of the *Encyclopedia of Endocrinology* by Hans Selye is a monumental documentation of most of the world's literature on the subject of ovarian tumors presented in outline loose leaf notebook fashion. An additional 427 page volume of bibliography accompanies the text. Many thousands of references have been collected, classified, and reviewed. This volume is part of an encyclopedia of endocrinology which according to the author, is a "first tentative effort to make the entire endocrine literature easily accessible to research

workers and clinicians. All bibliographical information has been carefully checked for correctness and the investigator seeking a basic bibliography on any phase of ovarian neoplasms will find it of incalculable help. The magnitude of the task has made it obviously impossible for the author to evaluate critically all of the assembled data as a result the reader will at times be somewhat confused by the mass of uncorrelated facts.

This text should unquestionably be available for reference purposes in the library of every teaching institution. It is doubtful if students or clinician will find it a satisfactory substitute for more orthodox textbooks of gynecological pathology.

cyanide solution is given. The vaginal speculum is introduced under aseptic conditions and material protruding from the vagina is removed but exploration is not done further than the internal cervical os. Five cubic centimeters of extract from the posterior pituitary lobe are given intramuscularly upon admission if the abortion is complete or incomplete. In threatened cases this is omitted.

2. In febrile or suspected criminal cases cervical smears and material for culture of aerobic and anaerobic organisms are taken from the uterine cervical canal. The material should be secured less than $\frac{1}{4}$ inch internally of the external cervical os.

3. Plasma should be given on admission if needed. Daily transfusions may be given to combat infection. The Rh factor of the blood for transfusion should be considered.

4. The entire head of the bed should be elevated about $\frac{1}{2}$ foot for postural drainage and the patient should be turned on her abdomen for an hour twice daily.

5. In any case with abnormal bleeding (complete or incomplete abortion) from 0.5 to 1 c.c. of pitocin ergotrate or obstetrical pituitary extract solution should be given every hour in the deltoid muscle for 3 doses and followed by a 1.320 gr. tablet of ergotrate per mouth every 4 hours for 6 doses. The same treatment should be given for endometritis.

6. Persistent hemorrhage may necessitate the use of a sponge stick or a curette or for packing only.

The author concludes that on the basis of his results the approach to the management of various types of abortion should be conservative. He points out that conservative treatment was unsuccessful in only 35 of the 2,406 cases of incomplete abortion.

JAMES F. DOWNELLY, M.D.

LABOR AND ITS COMPLICATIONS

Troile, D.: Induction of Labor by Means of Partergin. *An Ergot Alkaloid*. *Acta obst. gyn. scand.* 1947 27 94.

Partergin, a new ergot alkaloid is a watery solution of methyl-ergobasine-tartrate (1 c.c. of solution is equivalent to 0.075 mgm. of methergine). Previous reports have stated it to be free of the complications occurring after the administration of pure ergobasine.

To evaluate objectively the effect of partergin, labor was induced in 48 normal patients by 67 attempts at induction with this drug. The results have been compared with those obtained from 128 attempts at induction on 62 normal patients with pituitary preparation 1 c.c. of which equals 10 Voghtlin units. Fifty patients with normal spontaneous labors were used as controls.

When the fetus weighed 3,300 gm. or more, partergin was superior to pituitary for the induction of labor. If the fetal weight was less than 3,300 gm. the difference was not significant. The percentage of successful inductions with partergin was higher when the birth weight was 3,300 gm. or more (79.7%) than

when it was less than this weight (43.0%). No significant difference was demonstrated in the induction of labor between primiparas and multiparas. The medical induction of labor did not seem to increase the frequency of premature rupture of the membranes nor influence the duration of the parturition. No increase was noted in postpartum hemorrhage. There were no harmful effects upon the mothers.

Following the administration of partergin, a significant increase in the tension of the uterus was noted 10 times. In 3 of the 48 cases, fetal death occurred.

The authors advise against the use of partergin for the induction of labor if the fetus is alive.

GEORGE BLINCK, M.D.

Vikbladh, I.: Case of Ovarian Cyst Ruptured in Connection with Delivery. *Acta obst. gyn. scand.*, 1947 27 11.

The author reports a case of an unrecognized intra-partum rupture of a large ovarian cyst in a primigravida of 19 years, who on the day following rupture was delivered normally of a fully developed living male child. On the fourteenth postpartum day a laparotomy was performed for the presence of an ovarian cyst with ascites. There were found 2 to 3 liters of free clear gelatinous fluid in the peritoneal cavity and a left multilocular pseudomucinous cystoma 28 by 20 by 16 cm. with a perforation in the cyst wall. The cyst was extirpated and the post-operative course was uneventful. References to the rupture of ovarian cysts during pregnancy are briefly reviewed.

GEORGE BLINCK, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Bubis, J. L.: Puerperal Gynecology. *Am. J. Obs.* 1947 53 787.

The author reports a personal experience extending over a period of 30 years in the performance of repair operations for old, new or combined birth injuries immediately after delivery. In addition, he presents statistical reports of puerperal gynecology as practiced in the obstetric department of Mt. Sinai Hospital, Cleveland, Ohio from 1936 to 1946. The author states that time has not changed but rather has strengthened, his conviction that puerperal gynecology is feasible, safe, and of immeasurable value to the patient and should be universally adopted as an integral part of natal care.

The importance of repair of cervical lacerations is stressed, and the salient features of the surgical technique are reviewed. Repair of cystocele, rectocele, lacerations of the vaginal walls, and the management of hemorrhoids are discussed.

The experience of the author and his colleagues with thousands of operations performed immediately after delivery in a series of over 20,000 obstetric cases is presented to refute all possible objections to these procedures. Although such operations require special training, skill, and care, they have proved successful in the hands of many different surgeons.

origin. Retinopathy and neuropathy are two peripheral manifestations of angiospasm, a functional state. Convulsive seizures, which may or may not be preceded by albuminuria and hypertension, originate from a diencephalic center. In fact all of the symptoms of eclampsia seem to have their origin in the region of the hypothalamus.

The albuminuria of gestation and all its related symptoms seen in eclampsia can be ascribed to a functional derangement of the diencephalic and pituitary sympathetic centers, which are anatomically and functionally a unit. Gestation seems to set off the hypophysial infundibular mechanisms which appear in regular chronological order.

Estrogenic studies of diabetic pregnant women reveal that in all cases in which toxemia was present there was an abnormal level of estrogens and an elevation of gonadotropin this elevation preceding by several weeks the appearance of the pathological phenomena.

Gestation is not the only condition which gives rise to modified hormonal levels in the maternal or organism. There is no hormone specific to pregnancy and many changes that occur in pregnancy have their counterpart in the normal menstrual cycle.

It is not unreasonable to think that the albuminuria of pregnancy is no more than a peripheral manifestation of a general process of which the physiological mechanisms have their origin in the diencephalon and their course through the sympathetic nervous system, under endocrine regulation.

Ellis, J. T., Windham, S. W., Jr., McFatter, T. K., and Latholais, S. G. Spontaneous Rupture of the Uterus. *South. Surg.*, 1947 13 70.

The authors report in detail 2 cases of spontaneous rupture of the pregnant uterus. One patient was a primigravida of 4½ months gestation the other a 37 year old multigravida at term. In the case of the primigravida the condition is believed to be unusual in that sepsis following rupture of the uterus had resulted in a fistula of the abdominal wall through which a fetal hand was protruding. The multigravida was delivered of a living child by cesarean section though the fetus had been extruded completely into the peritoneum.

In America, rupture of the uterus occurs less frequently than in Europe because there is less pelvic distortion due to rickets and osteomalacia, and more medical supervision in obstetrics. The incidence of this condition as reported in large obstetrical centers, ranges from 1 in 95 to 1 in 4,000 deliveries. It occurs only rarely before the onset of labor. Balch in 1903, collected 78 such cases from the literature. Since that time the list has grown very gradually but the condition is still rare. The etiological factors include previous cesarean section, especially of the classical type, previous myomectomies, improper and energetic curettements, and previous pelvic infection. This last factor is considered one of the important predisposing causes to uterine rupture.

Microscopic study of these uteri show increased fibrous tissue in the uterine wall.

Rupture of the uterus before the onset of labor usually occurs in the fundus, whereas ruptures occurring during labor are more often in the lower uterine segment.

Practically all cases of spontaneous rupture of the uterus are in multiparas with an average of 4 to 6 siblings in the various groups reported.

The signs and symptoms in the order of frequency are bleeding, severe pain, abdominal tenderness, cessation of labor, shock, pallor, change in position of the fetus, syncope, blood in the urine, and distention. Two of these symptoms are emphasized; cessation of labor and blood in the urine. These symptoms plus abdominal tenderness should always be treated as rupture of the uterus.

The treatment of choice is laparotomy. Only by this means can a normal infant be delivered and the hemorrhage stopped and the uterus repaired or removed. Shock must be treated with sufficient blood or plasma. Infection must be combated by drainage, sulfadiazine, and penicillin.

The maternal mortality varies in the series reported from 50 to 100 per cent. The fetal mortality is about 90 per cent. In the authors' cases, both mothers died however one of the infants lived.

HARRY FIELDS, M.D.

Russell, P. D., Jr.: Abortions Treated Conservatively; a 12 Year Study Covering 2,739 Cases. *South. Surg.* 1947 40 3 4.

The author's cases of abortion are divided into three groups based upon the years in which they occurred. Further classification was based upon the clinical picture and was as follows:

- 1 Spontaneous with onset from no apparent cause
 - 2 Criminal with a history of an aborted patient or instrumentation.
 - 3 Complete with a history of pregnancy and the passage of products of conception. Little or no uterine activity
 - 4 Incomplete with a definite history of pregnancy and the passage of some part of the products of conception.
 - 5 Febrile, with a temperature of 100.4 F or more on 3 or more days after the first 24 hours, and with or without active signs of infection. (These patients should be isolated.) About one-fourth of the total will be in this group.
 - 6 Afebrile with no fever or active signs of infection on admission or during the convalescent period. About 75 per cent of the cases were in this group.
 - 7 Septic, with a history of abortion and the lapse of some time before admission of the patient to the hospital.
- A vaginal examination should be limited to the introduction of the speculum for smears. In general, the treatment is as outlined below:
- 1 The vulva should be prepared with sterile soap and shaved. A perineal douche of 1 to 1000 mercuric

larger than 9.3 cm. because, although the head may pass the plane of least pelvic dimensions well flexed the classical mechanism of extension is likely to enlarge the diameter so that 10 cm. should be the figure chosen in determining outlet contraction.

The author also believes that an anteroposterior measurement of 11.5 cm. while not absolutely ruling out contraction of the least pelvic plane does indicate that severe contraction is unlikely.

He cautions that the 9.3 centimeter diameter is an average and represents molding in flexion and that other conditions particularly breech presentation alter these diameters markedly. The soft tissue has been deliberately neglected to emphasize bony abnormalities.

Outlet contraction may show itself in various ways chiefly in the second stage of labor but also in the first and third stages. In the first stage uterine inertia may develop with hour glass contraction of the uterus.

Injuries to soft tissue may result from outlet contraction and also from springing of the symphysis pubis.

The treatment consists of antenatal planning in which one must decide to (a) allow labor at term (b) induce labor prematurely and (c) carry out elective cesarean section.

Labor should be carried out with conservatism, with analgesia during the first and second stages of labor. The author seems to favor postural treatment when the head is visible or easily palpable through the perineum, namely the exaggerated lithotomy position. If this fails, he favors the application of forceps especially in primigravida after deep episiotomy. Strict cephalic application should be made and the forceps used mainly for traction, and not rotation.

BYRON F. HESKETT, M.D.

Caso, Rogelio; Uranga Imaz, Francisco, A.; and Rozas, Francisco Fernández: Pelvic Separation (Disyunción pelviana). *Bolet. Soc. obst. ginec. B. Air.* 1946 25 540.

There are four grades of pelvic separation (1) complete separation of the cartilage without serious injury to the ligaments and hence without great separation of the margins (2) injury to the ligament great enough to permit considerable separation of the torn margins and an accompanying sacroiliac lesion (3) rupture complicated with injury to the skin, vagina, or bordering structures and (4) complete rupture of the symphysis pubis. The last is the extreme form.

X-ray has increased recognition of the entity and facilitates the diagnosis.

Fig. 1. (Caso et al.) Maneuvers used for diagnosis.

Fig. 2. Additional maneuvers used for diagnosis.

Prolonged labor or operation is the usual cause of the lesion.

Contributory factors are (1) local relaxation of the symphysis or tearing of the cartilage (2) size of the fetus (3) prolonged labor, the mechanism of labor (the passage of the fetal head through the pelvic ring) or intense abdominal contractions (4) application of the forceps, (5) simple dystocia because of stretching of the pelvic ring, (6) trauma (7) age of the patient (8) multiparity and (9) medical mismanagement.

The diagnosis of sacroiliac complication is facilitated by maneuvers shown in Figures 1 and 2. Pain is aggravated by each movement.

Complications include hemorrhage, injury to the urinary mechanism, complete rupture to the extensor associated fracture, and infection.

Treatment consists in prophylaxis if a diastasis exists or is likely to occur and proper measures should be taken even during the course of the labor. Immediate therapy consists of (1) immobilization in bed between sand bags (2) pelvic bandaging and use of the hammock (3) corseting and bandaging and (4) bandaging with continuous weighted extension.

Suturing of the symphysis has been abandoned as definitive treatment. Dubrovsky has advocated a body cast with a turn screw which permits tightening as indicated.

STEPHEN A. ZIEGLER, M.D.

Advantages to the mother include improved general health, saving of time and money, prophylaxis against subsequent disabilities, and probable protection from cancer in later life.

JOHN R. WOLFF M.D.

Hodgkinson, C. P.: Penicillin and Acute Puerperal Mastitis. *Am. J. Obs.*, 1947 53 834.

The author reports his experience in the treatment of 73 cases of infected breasts observed since 1942, all but 7 of which developed in the postpartum period.

In the group with puerperal mastitis, 18 patients, when first seen, were suffering from abscesses. Sixteen of the breasts required incision and drainage, while 2 cleared after aspiration. Forty-eight patients were treated with intramuscular penicillin during the cellulitis phase of the disease, with complete resolution in each instance. This response was reflected by the evident decrease in morbidity which averaged 6.1 hospital days. In contrast, the surgically treated group required 42.3 days from onset to complete healing.

Because penicillin is not secreted in the milk in sufficient amounts to control contaminating staphylococci, it is believed advisable to inhibit lactation to prevent reinfection of the breast.

Sulfonamide therapy is not recommended as a substitute for early penicillin therapy. Before penicillin became available 13 patients were treated during the cellulitis phase of the disease with various sulfonamides in apparently adequate dosage; 9 patients required incision and drainage of an abscess, giving a failure of 75 per cent and 4 patients were admitted for penicillin treatment after having failed to respond to sulfadiazine. All promptly resolved when penicillin was given.

Morris, W. I. C.: Outlet Contraction of the Pelvis. *Edinburgh M. J.* 1947 54 90.

The author states that there is no great unanimity with regard to the incidence or even the existence of outlet contraction of the pelvis. The incidence varies, with the author quoted from 6 to 26 per cent and there are those who minimize its importance. In the present article diagnostic criteria which might prove helpful in outlet contraction are examined.

Normally as the fetal head meets outlet resistance it is molded in full flexion so that it approximates a cylinder with biparietal, suboccipitobregmatic, and occipitofrontal diameters, all about equal averaging 9.3 cm. or the largest diameter if the head remains in flexion. During extension, an oblique measurement must pass the outlet roughly this is 10 cm.

The axis of advance of the fetal head through the pelvis makes almost a right angle bend to get to the outlet.

Bony contraction of the outlet may result from (a) absolute narrowing at the plane of least pelvic

dimensions, (b) narrowing below the level of this plane or narrowing of the pubic arch, and (c) combinations of "a" and "b." The first of these may involve either the coronal or sagittal measurements of the outlet. The narrowing may be a general funneling of the entire pelvis, frequently associated with android pelvis, high assimilation pelvis, and some spinal deformities, or an isolated narrowing frequently seen with prominent ischial spines or unusual convergence of the lower sacrum towards the symphysis pubis. Narrowing of the pubic arch is usually independent of any other alteration of the pelvis and results in reduction in available anteroposterior space for the advancing head and may result in interference with internal rotation and increased perineal trauma.

The author mentions the various ways of measuring the pelvic outlet, points out their inadequacies and suggests an engineering principle, namely the use of a gauge in assessing the caliber of an irregular aperture, or a gauge with a diameter of 9.3 cm. In fitting this gauge into the dried pelvis two points are made: (1) the distance between the pubic arch and the cylinder should not exceed 1 cm. and (2) the coronal diameter of the cylinder should be at least 1 cm. in front of the ischial tuberosities.

In measuring the living subject the author describes x-ray pelvimetry and the technique which he employed. In addition, a transparency on which is outlined a circle of 9.3 cm. diameter is superimposed on the x-ray film. The lateral film permits one to make allowances for a narrowed pubic arch angle by correcting the anterior and posterior diameter to what the author calls the "corrected anteroposterior diameter of the outlet."

Cases are illustrated, with diagrams of some of the abnormal findings.

Clinically the following measurements are taken: (a) the anteroposterior of the least pelvic plane (b) the intertuberischial, (c) the posterior sagittal and (d) the anterior sagittal. Attempts are also made to form subjective impressions of (a) the amplitude of the pubic arch and (b) the distance between the ischial spines. The author believes the only measurement that can be taken accurately is the anteroposterior diameter of the least pelvic plane. The other vaginal measurements are described and their inaccuracies discussed.

By taking the anteroposterior diameter of the plane of least pelvic dimensions one can at least pick out the cases for complete x-ray pelvimetry.

He states that with x-ray pelvimetry the diagnosis of a contracted outlet may be made with complete confidence if the anteroposterior or transverse diameter of the plane of least pelvic measurement is less than 9.3 centimeters, admitting that slight narrowing in one direction may be compensated for if the other diameter is larger and assuming that some molding is possible. He suggests that the measurement which he has referred to as the "corrected anteroposterior diameter of the outlet" can be taken as an index of outlet contraction, but states the critical figure is

is probably the most important factor in stone formation. The calcium level is influenced by parathormone, vitamin D serum protein and the serum phosphorus, with which last it varies inversely. Hypocalcemia is present in hyperparathyroidism hypervitaminosis D, uremia, and many diseases of bone, the principal endogenous source of calcium 70 to 90 per cent of calcium is excreted in the feces and 10 to 30 per cent in the urine 30 per cent of phosphorus is excreted in the feces and 70 per cent in the urine. Vitamin D and the acid ash diet increase calcium elimination. An excessive chloride acidosis increases the urinary excretion of calcium and is most marked in the case of ammonium chloride. The metabolism of citric acid has a definite relationship to the formation of renal calculi. Citric acid is present in large quantities in bone, where it is interrelated with calcium. The amount of urinary citric acid increases in an alkaline and decreases in an acid urine. The presence of the citrate-ion influences the ionization of calcium, tending to replace the calcium ion participating in the precipitation of calcium phosphate by the readily ionized soluble calcium citrate complex. It has been shown in many cases of recurrent renal calculi without infection that subnormal amounts of citric acid and excessive amounts of calcium are present in the urine. Estrogens increase urinary citric acid without affecting the hydrogen ion concentration and they also lower the output of calcium.

The administration of aluminum hydroxide gel forms the highly insoluble aluminum phosphate in the gut and much reduces the absorption of phosphorus. This prevents the precipitation of calcium phosphate in the urine.

Acidifying agents lower the urinary excretion of citrate and increase that of calcium thus keeping the urine saturated and only capable of dissolving the endogenous calcium phosphate without being able to dissolve any existing calcium phosphate deposits in other words to inhibit further stone growth but not to remove stones already present.

The indications for surgical intervention are obstruction of the drainage mechanism of the kidney as evidenced by dilatation shown on intravenous urography especially if there is no likelihood of the stone being passed naturally. Any evidence of failing function in the obstructed part and especially any suggestion of the onset of infection demands active intervention.

Nonoperative treatment is indicated under the following conditions (1) limitation of the calculi to the cortical part of the kidney where they have no macroscopic connection with a calyx (2) mobile stones causing no obstruction, and of such size as to make passage per vias naturales possible (3) stones composed of calcium phosphate or mixed phosphatic stones (4) bilateral stones associated with gross disease and limited function in both kidneys, rendering any operation hazardous.

Much can be done by forced fluids, by correction of faulty diet and by attempts to control superadded

infection. In the case of decubitus calculi or stones consisting wholly or largely of phosphates attempts may be made to dissolve the calculi by the use of Suby's solution G and it is most important to bring this about before secondary infection supervenes particularly with urea splitting organisms, which render the stones relatively insoluble. Sometimes dissolution will proceed satisfactorily and then be arrested owing to the stone having a part composed of some insoluble salt such as oxalate nevertheless, it may have brought about such a reduction in size as to render the natural passage of the stone possible.

Another cause of possible difficulty is a slowing down or cessation of dissolution in solution G due to the deposition of a mucoid gelatinous covering on the surface of the stone. If a 0.5 per cent solution of urease be substituted for a few hours this envelope is dissolved and solution G may again prove effective.

For surgical exposure the author favors an incision in the line of the twelfth rib with subperiosteal resection of the rib at the posterior end of the incision. Calculi should be removed by pyelolithotomy if possible. Nephrolithotomy has always seemed to be an undesirable operation to the author because of the nightmare of secondary hemorrhage which may necessitate a secondary nephrectomy especially where the kidney is grossly infected. He also favors a nephrostomy tube in cases in which dilatation has resulted from the presence of a stone. The presence of the tube renders lavage of the pelvis much easier if it becomes necessary.

Calicectomy or partial nephrectomy is a very useful procedure in preventing stone recurrence, particularly when a ragged cavity remains in the lower pole of the kidney after the removal of a stone. Post operative hemorrhage is less likely from the resulting cleanly incised and accurately approximated area of renal tissue than from an incision into a ragged infected cavity surrounding a calculus.

In the presence of bilateral stone, considerable judgment is required in deciding whether to operate at all or which side to approach first. Nephrectomy or even nephroureterectomy may prove the wisest course as the infected calculus kidney seldom if ever returns to complete normality. When however the disease is bilateral conservative surgery even if it leaves a second rate kidney in the end may be the only possibility.

Ureteric calculi. The indications for active surgical intervention in the case of ureteric calculus are the same as in the case of renal calculus, that is, dilatation of the upper urinary tract above the stone particularly if infection is superadded. If neither dilatation nor infection is present a conservative attitude can be adopted indefinitely. The rapid rate at which an obstructed kidney may become totally destroyed once infection gains a foothold must however be kept in mind.

A smooth ureteric stone may retreat into the renal pelvis, thereby relieving obstruction of the kidney. Retreat of a ureteric calculus may sometimes be brought about by preliminary investigations and

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

MacDonald, S. A., and Matthews, W. H.: Fibrin Foam and Gelfoam in Kidney Wounds. *J. Urol.*, Balt., 1947 57 802.

Two hemostatic agents, (1) fibrin foam, a by-product of fractionation of human blood plasma, and (2) gelfoam, a synthetic made from gelatin solution, were investigated for the purpose of comparing their local effect on tissues following implantation in the kidney.

For this study, large nephrotomy wounds were made in a dog's kidney completely excising either pole and extending almost to the renal pedicle. In all experiments, gelfoam or fibrin foam was laid in the wound, which was then closed by mattress sutures in the capsule only. The kidneys were removed at six day intervals, the longest observation period being 24 days in the case of fibrin foam, and 36 days with gelfoam. In no instance was there any evidence of postoperative bleeding. The excised kidneys were examined grossly and microscopically with the following findings.

All showed uninterrupted healing with no discernible difference in the rate or character of healing. Microscopically there was no marked inflammatory or foreign-body reaction in the wounds.

The absorption process of the two substances seems to be entirely different. Fibrin foam disappears quite rapidly and undergoes rapid liquefaction. The wound defect fills with granulation tissue, with considerable inflammatory cell exudate then the usual process of cellular proliferation and fibrosis occurs. The gelfoam wounds show many strands of the substance acting as a scaffolding on which granulation tissue and fibroblastic cells are laid down. Associated with the fibroblasts are many multi-nucleated giant cells. This gelfoam framework gradually disappears and is replaced by collagen deposits in which the process of healing is completed.

In every instance, fibrin foam was almost completely absorbed in 12 days, and totally absorbed in 18 days. Gelfoam absorbed slowly, requiring 24 days for any noticeable diminution, and some gelfoam was found in the 30 and 36-day specimens. Despite the slow rate of autolysis, the gelfoam substance does not produce any corresponding increase in fibrous or foreign-body reaction.

A detailed report on specimens of each substance is given.

ROBERT O. BEADLES, M.D.

Robinson, R. H. O. B.: Some Problems of Renal Lithiasis. *Proc. R. Soc. M. Lond.*, 1947 40. 301

This very thorough study deals with some particular problems bearing on the etiology, diagnosis, and treatment of stone in the upper urinary tract.

A distinction is drawn between fixed and mobile renal calculus, the latter term referring to a stone

which can migrate within the pelvis and calyces, usually being of such size as to be capable of temporarily obstructing the ureter and thereby predisposing to dilatation and stasis behind it.

Calcification (type I and type II of Randall) is also mentioned. In the latter an intratubular calcification results from excessive excretion of calcium phosphate, and actual deposition occurs in the walls of the tubules as a result of degenerative changes in them associated with defective blood supply or toxic irritants. In the former an interstitial papillary calcium plaque develops, probably as a result of a response of the kidney to toxins.

Stones develop at a rapid rate in patients who are immobilized in the supine position and are due to stasis alone. The tendency to precipitation is increased when calcium metabolism is upset, partly by disuse atrophy of bone, and by bone disease or bone trauma. These calculi are composed primarily of calcium phosphate, soft and coralline in structure and are situated in the most dependent calyces. They tend to disperse rapidly if the kidney can be flushed by getting the patient out of bed. Frequent x rays are advisable in recumbent cases. The normally acid urine becomes rapidly alkaline on immobilization. Hence, an acid ash diet and ammonium salts should be given. Mineral oil aperients are undesirable because they lead to deficient absorption of Vitamin A.

The close relationship between infection and stone is also mentioned, attention being drawn to the fact that the organisms in the kidney urine may change from time to time.

Prolonged exposure to heat and sun in hot climates has a definite influence upon the incidence of renal calculus. White races appear to have a higher susceptibility than black.

Calculi associated with hyperparathyroidism are a well recognized group at the present time, but a point which is not so well appreciated is that they can occur without any lesions of the bony skeleton. There is a close relationship between vitamin D deficiency and hyperparathyroidism, vitamin D aiding in the absorption of calcium from the intestinal tract while the parathyroids mobilize it from osseous tissue.

Deficiency of vitamin A disturbs the calcium phosphate ratio and produces changes in the epithelium of the urinary tract.

Oxamide and sulfonamide calculi are obvious instances of crystallization due to the hypersecretory state in which the colloid can no longer hold the excess crystalloid in solution. Oxalates produce secondary deposition on pre-existing calcium plaques especially if hyperoxalemia and hyperoxaluria are present. Oxaluria may be due to a disturbed calcium-phosphorus ratio or to an incomplete oxidation of carbohydrates. Calcium-phosphorus metabolism

is probably the most important factor in stone formation. The calcium level is influenced by parathormone vitamin D serum protein and the serum phosphorus, with which last it varies inversely. Hypocalcaemia is present in hyperparathyroidism, hypervitaminosis D, uremia, and many diseases of bone the principal endogenous source of calcium 70 to 90 per cent of calcium is excreted in the feces and 10 to 30 per cent in the urine 30 per cent of phosphorus is excreted in the feces and 70 per cent in the urine. Vitamin D and the acid ash diet increase calcium elimination. An excessive chloride acidosis increases the urinary excretion of calcium and is most marked in the case of ammonium chloride. The metabolism of citric acid has a definite relationship to the formation of renal calculi. Citric acid is present in large quantities in bone, where it is interrelated with calcium. The amount of urinary citric acid increases in an alkaline, and decreases in an acid urine. The presence of the citrate-ion influences the ionization of calcium, tending to replace the calcium ion participating in the precipitation of calcium phosphate by the readily ionized soluble calcium citrate complex. It has been shown in many cases of recurrent renal calculi without infection that subnormal amounts of citric acid and excessive amounts of calcium are present in the urine. Estrogens increase urinary citric acid without affecting the hydrogenion concentration and they also lower the output of calcium.

The administration of aluminum hydroxide gel forms the highly insoluble aluminum phosphate in the gut and much reduces the absorption of phosphorus. This prevents the precipitation of calcium phosphate in the urine.

Acidifying agents lower the urinary excretion of citrate and increase that of calcium thus keeping the urine saturated and only capable of dissolving the endogenous calcium phosphate without being able to dissolve any existing calcium phosphate deposits in other words to inhibit further stone growth but not to remove stones already present.

The indications for surgical intervention are obstruction of the drainage mechanism of the kidney as evidenced by dilatation shown on intravenous urography especially if there is no likelihood of the stone being passed naturally. Any evidence of failing function in the obstructed part and especially any suggestion of the onset of infection demands active intervention.

Nonoperative treatment is indicated under the following conditions (1) limitation of the calculi to the cortical part of the kidney where they have no macroscopic connection with a calyx (2) mobile stones causing no obstruction, and of such size as to make passage per vias naturales possible (3) stones composed of calcium phosphate or mixed phosphatic stones (4) bilateral stones associated with gross disease and limited function in both kidneys, rendering any operation hazardous.

Much can be done by forced fluids, by correction of faulty diet and by attempts to control superadded

infection. In the case of decubitus calculi or stones consisting wholly or largely of phosphates attempts may be made to dissolve the calculi by the use of Suby's solution G and it is most important to bring this about before secondary infection supervenes particularly with urea-splitting organisms which render the stones relatively insoluble. Sometimes dissolution will proceed satisfactorily and then be arrested owing to the stone having a part composed of some insoluble salt such as oxalate nevertheless it may have brought about such a reduction in size as to render the natural passage of the stone possible. Another cause of possible difficulty is a slowing down or cessation of dissolution in solution G due to the deposition of a mucoid gelatinous covering on the surface of the stone. If a 0.5 per cent solution of urease be substituted for a few hours this envelope is dissolved and solution G may again prove effective.

For surgical exposure the author favors an incision in the line of the twelfth rib with subperiosteal resection of the rib at the posterior end of the incision. Calculi should be removed by pyelolithotomy if possible. Nephrolithotomy has always seemed to be an undesirable operation to the author because of the nightmare of secondary hemorrhage, which may necessitate a secondary nephrectomy especially where the kidney is grossly infected. He also favors a nephrostomy tube in cases in which dilatation has resulted from the presence of a stone. The presence of the tube renders lavage of the pelvis much easier if it becomes necessary.

Callicectomy or partial nephrectomy is a very useful procedure in preventing stone recurrence, particularly when a ragged cavity remains in the lower pole of the kidney after the removal of a stone. Post operative hemorrhage is less likely from the resulting cleanly incised and accurately approximated area of renal tissue than from an incision into a ragged infected cavity surrounding a calculus.

In the presence of bilateral stone, considerable judgment is required in deciding whether to operate at all or which side to approach first. Nephrectomy or even nephroureterectomy may prove the wisest course as the infected calculus kidney seldom if ever returns to complete normality. When however the disease is bilateral conservative surgery even if it leaves a second rate kidney in the end may be the only possibility.

Ureteric calculi. The indications for active surgical intervention in the case of ureteric calculus are the same as in the case of renal calculus, that is dilatation of the upper urinary tract above the stone particularly if infection is superadded. If neither dilatation nor infection is present a conservative attitude can be adopted indefinitely. The rapid rate at which an obstructed kidney may become totally destroyed once infection gains a foothold must however be kept in mind.

A smooth ureteric stone may retreat into the renal pelvis, thereby relieving obstruction of the kidney. Retreat of a ureteric calculus may sometimes be brought about by preliminary investigations, and

this fact emphasizes the importance of x-ray control immediately before or preferably if necessary during operation.

In the case of the pelvic portion of the ureter spontaneous passage of calculi occurs in a high proportion of cases (90 per cent in the author's) although some time may be taken in the process.

Of the instrumental methods, the author has found the use of an indwelling ureteric catheter (passed alongside the stone and kept *in situ* for 48 hours) the most satisfactory method. If the Howard cork-screw or the Councilll umbrella extractor is used, it is always wise to insert an indwelling ureteric catheter to counteract the effects of reactionary edema. The author is very apprehensive of their use, despite the results that have been achieved.

Actual meatotomy of the ureteric orifice is seldom necessary and is better avoided because of the risks of troublesome hemorrhage and, more important, ureteric incompetence with vesicorenal reflux.

If instrumentation fails operation is indicated. The author employs both the midline and inguinal approaches. The latter is simpler but if the stone is very low he prefers the former. Under certain conditions a transperitoneal approach may have great advantages, particularly in women.

Mentha, C.: Roentgenographic Examination of the Bladder; Stereopneumocystography (L'examen radiologique de la vessie (stéréo-pneumocystographie) *J. urol. méd. Par.* 1946-1947 53 89.

The author describes a new method to visualize X-ray transparent objects in the bladder such as soft calculi, diverticula, and tumors of the bladder or of the prostate. He uses as contrast medium a mixture of air and an iodine containing compound.

After emptying the bladder completely with a catheter 20 c.c. of the contrast medium Roche and

Fig. 2 (Mentha) Interpretation of the stereoscopic view of Fig.

100 c.c. of air are injected through the same catheter which remains in place and is clamped off.

Simple roentgen pictures so obtained are very hard to interpret. The irregularities of the floor and the walls, and the muscular ridges of the bladder give a whole scale of shades and capacities of different degree which make the picture confusing. To overcome this difficulty, the author devised a method to obtain stereoscopic pictures. The distance of the anticathode to the film is 80 cm. Two films in a case are placed under the patient, the tube is focused from 1 to 2 fingerbreadths above the symphysis, and 2 pictures are taken at a distance of 4 cm. from each other. From these stereoscopic pictures the author constructed models made of paste to illustrate the findings. WENZEL M. SCHWARTZ, M.D.

Ney, C., Auerbach, O., and Hoen, T. L.: Pseudosphincter in Neurogenic Bladder *J. Urol. Balt.* 1947 57 858.

During the course of studies on the neurogenic bladder the authors observed a definite sphincter-like structure lying between the internal and external urethral sphincters. To their knowledge, this finding has not been previously described.

This structure, which the authors have designated a pseudosphincter for reasons which will become apparent, was clearly seen in 8 cases of a total of 21 paraplegics studied. It was situated in the prostatic urethra just distal to the colliculus seminalis in the region of the inferior crista. In half of the cases the pseudosphincter was pale with a sharp edge and although completely surrounding the urethra, its dorsal side more or less tapered into the inferior crista which still could be seen throughout its entirety. In the remaining 4 cases, the pseudosphincter was more fully developed. It was pinkish, edged with a well rounded corrugated edge, and its dorsal side was raised above the level of the inferior crista which, although obliterated at this level, could still be seen running

GENITAL ORGANS

distally from the pseudosphincter. In every instance the pseudosphincter projected into the lumen of the prostatic urethra to an extent that made it impossible to be overlooked.

The prostatic urethra, in the 8 cases, was dilated varying from an early funnel urethra to one with a large sacular dilatation and the pseudosphincter always formed the distal boundary of the dilated portion. At first it was thought that the dilated sphincter might be a relative structure formed as a result of disparity between the size of the lumen of the proximal prostatic urethra and its distal portion. Further study obviated this possibility. In the first place mere dilatation should produce a sphincteric appearance only when looking toward the narrow lumen from the dilated portion not when viewing the structure from the opposite side. In the second place, 8 other cases with dilated posterior urethras showed only a tendency to pseudosphincter formation; the structure was so poorly defined in these cases that the authors considered it unjustifiable to label it a pseudosphincter. In the third place, in the 8 cases in which it was definitely present, the pseudosphincter was conspicuous under all conditions of examination, i.e. whether the water was running or not, and whether the scope was close to the structure or with drawn for a distance.

Transurethral resection was performed on 3 of the cases merely to obtain suitable specimens of the pseudosphincter and internal sphincter for microscopic study and not as a method of treatment. These two structures were resected separately and individual bites were removed immediately and not permitted to float back into the bladder. These precautions prevented any possible confusion as to origin of the pieces.

The findings in the 3 cases were similar. Microscopic examination of the pseudosphincter revealed transitional epithelium lining the structure. The tissue which was hyalinized in areas. There was an extensive acute and chronic inflammatory process with edema which threw the overlying epithelium into folds. The inflammatory cells were densely arranged and located chiefly in the subepithelial tissue and they were composed of lymphocytes polymorphonuclear leucocytes mononuclears and histiocytes intermingled in a rich number of distended capillaries. The submucosal glands were lined by plasma. There was a small amount of muscle tissue found with Van Gieson stain. Portions of the prostate lying at the base of the pseudosphincter showed evidence of chronic inflammatory processes in which there were periglandular collections of lymphocytes and mononuclear cells and an increase of interstitial connective tissue. Compared with sections of the internal sphincter taken at the same sitting the latter was also lined by transitional epithelium showing a similar but less extensive inflammatory process. The wall however contained abundant muscle bundles.

JOHN A. LOER, M.D.

Landsteiner, R. K. and Brown H. P.: Observations on the Treatment of Carcinoma of the Prostate by Orchestomy. *Am J M Sc.* 1947 213 450.

The effects of orchectomy in 35 cases of carcinoma of the prostate were studied. The patients were observed for periods varying from 6 months to 4 years. They varied in age from 53 to 87 years. Of the 35 patients 20 had a positive microscopic diagnosis of carcinoma of the prostate while in the remaining 15 the diagnosis was made by physical findings elevated acid phosphatase and roentgen ray evidence of bony metastases.

Of the patients having metastases, approximately two-thirds experienced moderate to severe pain preoperatively. In practically all of the cases, surgical castration was followed by amelioration of symptoms within 48 hours. This rapid response suggests that pain as such is due more likely to pressure on or actual involvement of the nerves by carcinoma (usually in the lymphatics or lymph nodes) rather than by intraosseous growth which will show no detectable change by the roentgen ray in so short a time. Little improvement can be expected in cases in which the bony metastases destroy the normal contour of the vertebral column. On the other hand where pain is caused by peripheral nerve involvement, one may expect relief in a majority of the cases.

Along with other observers the authors have found that patients who were bedridden and received large doses of opiates were able in several instances to resume their former occupations and no longer required sedation.

As might be expected improvement in well being and appetite paralleled relief of pain in almost all instances. This improvement may be very rapid and dramatic.

In the present series of 35 cases 18 patients had evidence of metastases as seen by the roentgen ray. In the bones there were no constant changes which frequently the osteoplastic metastases became more calcified and appeared more discrete. In a few cases there was no significant change, and two cases only showed decreased density of the osteoplastic lesions with a partial restoration of normal bone architecture.

A very favorable change in the roentgen ray appearance of metastases occurred in one of 2 patients having metastases to the lung fields.

Several patients who showed a progression of metastases by roentgen ray did so in spite of marked clinical improvement.

Although a decrease in size and softening of the original lesion in the prostate was observed in about one third of the patients treated only 5 showed a finished residual urine. This is not surprising when one considers that in many cases obstruction to urination is contributed to or wholly caused by

this fact emphasizes the importance of x ray control immediately before or preferably if necessary during operation.

In the case of the pelvic portion of the ureter spontaneous passage of calculi occurs in a high proportion of cases (90 per cent in the author's) although some time may be taken in the process.

Of the instrumental methods, the author has found the use of an indwelling ureteric catheter (passed alongside the stone and kept *in situ* for 48 hours) the most satisfactory method. If the Howard corkscrew or the Concill umbrella extractor is used, it is always wise to insert an indwelling ureteric catheter to counteract the effects of reactionary edema. The author is very apprehensive of their use despite the results that have been achieved.

Actual meatotomy of the ureteric orifice is seldom necessary and is better avoided because of the risks of troublesome hemorrhage and more important ureteric incompetence with vesicorenal reflux.

If instrumentation fails operation is indicated. The author employs both the midline and inguinal approaches. The latter is simpler but if the stone is very low he prefers the former. Under certain conditions a transperitoneal approach may have great advantages, particularly in women.

PRELIMINARY PROGRAM FOR 1947 CLINICAL CONGRESS, THE WALDORF ASTORIA, NEW YORK, SEPTEMBER 8 TO 12 1947

THE American College of Surgeons will hold its thirty third annual Clinical Congress in New York from September 8 to 12 with headquarters at The Waldorf Astoria. The five-day program includes operative and nonoperative clinics, scientific sessions in surgery and the surgical specialties, hospital conferences, showings of medical motion pictures, official meetings, and educational and technical exhibits. As one of the leading medical events of the year the Clinical Congress provides excellent opportunities for presentation of the latest developments in surgery and related fields, and its educational value for the individual surgeon and the entire profession is well recognized.

All types of instructional methods are employed first hand observation in the operative clinics visual demonstration in nonoperative clinics and in surgical films lecture type presentations in symposia formal addresses, such as the Presidential Address and the Martin Memorial Lecture forums in which a great many speakers can participate informal panel discussions in which descriptions of new ideas and techniques may be described and commented upon scientific exhibits in which developments in surgery and activities related thereto are portrayed in chart and graph form and displays of new equipment and other products in which technical developments which increase the efficiency of the surgeon may be studied

CLINICS

The New York Committee on Arrangements has appointed a clinic committee composed of representatives of the New York hospitals which will participate in the clinical program. Every effort is being made by both of these committees to insure a clinic program that will give the visiting surgeons a comprehensive idea of the surgical resources of the New York metropolitan area, with the program of the general hospitals arranged to cover clinics in general surgery obstetrics and gynecology fractures, orthopedic surgery thoracic surgery neurosurgery genitourinary surgery and ophthalmology and otolaryngology. Special hospitals will also arrange clinics in their fields. General and special demonstrations will be held on subjects such as fractures, cancer maternal morbidity and end-result studies newer diagnostic and therapeutic procedures preoperative and postoperative supportive treatment anesthesia and reconditioning

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening September 8 in the Grand Ballroom. The program will include the inaugural ceremony for the incoming officers. Dr. Irvin Abell will give the Presidential Address. Dr. Allen O. Whipple of New York, Clinical Director of Memorial Hospital for the Treatment of Cancer and Allied Diseases will present the second Martin Memorial

distally from the pseudosphincter. In every instance the pseudosphincter projected into the lumen of the prostatic urethra to an extent that made it impossible to be overlooked.

The prostatic urethra, in the 8 cases, was dilated varying from an early funnel urethra to one with a large saccular dilatation and the pseudosphincter always formed the distal boundary of the dilated portion. At first it was thought that the pseudosphincter might be a relative structure, formed as a result of disparity between the size of the lumen of the proximal prostatic urethra and its distal portion. Further study obliterated this possibility. In the first place mere dilatation should produce a sphincteric appearance only when looking toward the narrow lumen from the dilated portion, not when viewing the structure from the opposite side. In the second place, 8 other cases with dilated posterior urethras showed only a tendency to pseudosphincter formation; the structure was so poorly defined in these cases that the authors considered it unjustifiable to label it a pseudosphincter. In the third place, in the 8 cases in which it was definitely present, the pseudosphincter was conspicuous under all conditions of examination, i.e. whether the water was running or not, and whether the scope was close to the structure or withdrawn for a distance.

Transurethral resection was performed on 3 of the cases merely to obtain suitable specimens for microscopic study and not as a method of treatment. These two structures were resected separately and individual bites were removed immediately and not permitted to float back into the bladder. These precautions prevented any possible confusion as to origin of the pieces.

The findings in the 3 cases were similar. Microscopic examination of the pseudosphincter revealed transitional epithelium lining the structure. The wall was composed of loose and dense connective tissue which was hyalinized in areas. There was an extensive acute and chronic inflammatory process with edema which threw the overlying epithelium into folds. The inflammatory cells were densely arranged and located chiefly in the subepithelial tissue and they were composed of lymphocytes, polymorphonuclear leucocytes, mononuclears, and histiocytes intermingled in a rich number of distended capillaries. The submucosal glands were lined by transitional epithelium and showed marked hyperplasia. There was a small amount of muscle tissue found with Van Gieson stain. Portions of the prostate lying at the base of the pseudosphincter showed evidence of chronic inflammatory processes in which there were periglandular collections of lymphocytes and mononuclear cells and an increase of interstitial connective tissue. Compared with sections of the internal sphincter taken at the same sitting the latter was also lined by transitional epithelium showing a similar but less extensive inflammatory process. The wall however contained abundant muscle bundles.

GENITAL ORGANS

Landsteiner, E. K. and Brown, H. P.: Observations on the Treatment of Carcinoma of the Prostate by Orchiectomy. *Am. J. M. Sc.* 1947 213 450

The effects of orchiectomy in 35 cases of carcinoma of the prostate were studied. The patients were observed for periods varying from 6 months to 4 years. They varied in age from 53 to 87 years. Of the 35 patients 20 had a positive microscopic diagnosis of carcinoma of the prostate while in the remaining 15 the diagnosis was made by physical findings, elevated acid phosphatase and roentgen ray evidence of bony metastases.

Of the patients having metastases, approximately two-thirds experienced moderate to severe pain preoperatively. In practically all of the cases surgical castration was followed by amelioration of symptoms within 48 hours. This rapid response suggests that pain as such is due more likely to pressure on or actual involvement of the nerves by carcinoma (usually in the lymphatics or lymph nodes) rather than by intraosseous growth which will show no detectable change by the roentgen ray in so short a time. Little improvement can be expected in cases in which the bony metastases destroy the normal contour of the vertebral column. On the other hand where pain is caused by peripheral nerve involvement one may expect relief in a majority of the cases.

Along with other observers, the authors have found that patients who were bedridden and required large doses of opiates were able, in several instances, to resume their former occupations and no longer required sedation.

As might be expected improvement in well being and appetite paralleled relief of pain in almost all instances. This improvement may be very rapid and dramatic.

In the present series of 35 cases 18 patients had evidence of metastases, as seen by the roentgen ray. In the bones there were no constant changes which could be interpreted as signifying regression. Most frequently the osteoplastic metastases became more calcified and appeared more discrete. In a few cases there was no significant change, and two cases only showed decreased density of the osteoplastic lesions with a partial restoration of normal bone architecture.

A very favorable change in the roentgen ray appearance of metastases occurred in one of 2 patients having metastases to the lung fields.

Several patients who showed a progression of metastases by roentgen ray did so in spite of marked clinical improvement.

Although a decrease in size and softening of the original lesion in the prostate was observed in about one third of the patients treated only 5 showed a resulting improvement of urinary function and diminished residual urine. This is not surprising when one considers that in many cases obstruction to urination is contributed to or wholly caused by

benign prostatic hypertrophy which so often occurs together with carcinoma of the prostate.

The authors are of the opinion that if urinary symptoms are severe enough to suggest need for operative interference this should be performed at the same time as orchectomy rather than to wait for possible improvement from orchectomy alone.

Of the 23 patients with metastases, 21 had acid phosphatase values above 4 units. All 21 cases displayed a reduction in the acid phosphatase level after surgical castration, 12 of them ultimately returning to normal. In the authors' experience this is of no prognostic significance since a number of the patients whose acid phosphatase became normal and remained within normal limits succumbed within 3 to 10 months.

Unfortunately there are few if any clinical or laboratory clues which enable one to foretell how any one patient will respond to surgical castration. The length of time during which a patient may be benefited by castration and remain free of pain varies considerably. The shortest period of improvement among the authors' cases was 3 months, while the longest period of improvement to be followed by relapse lasted 24 months. As a rule, the reappearance of pain was coincidental with a rapid deterioration of the patient's general condition and was soon followed by death.

The question of the optimal time for orchectomy has remained unanswered. Many urologists advise withholding orchectomy until metastases or symptoms thereof appear. It has been the policy of the authors in most cases to perform orchectomy whenever the diagnosis of carcinoma of the prostate is made regardless of the presence or absence of metastases.

FREDERICK A. LLOYD M.D.

MISCELLANEOUS

Kretschmer H. L.: Genitourinary Conditions in Infants and Children. *J. Pediatr.* 3 Louis, 1947, p. 603.

A steady stream of contributions by numerous authors have emphasized that age can no longer be used as an alibi against complete urologic examination in infancy and childhood as, in general, the indications and contraindications for cystoscopy in children and adults are identical. The increasing enlightenment in the realm of pediatric urology has helped to alleviate suffering in the young and prevent much unnecessary invalidism in adult life.

Anomalies of the urinary tract. With the routine use of intravenous urography these have been found to be far more common than was formerly supposed. The mere presence of an anomaly does not indicate surgery unless the former has produced changes such as stone hydronephrosis, and recurring attacks of pyelonephritis. When pyuria persists longer than 4 or 6 weeks despite intensive medical therapy a complete urological examination should be carried out.

Supernumerary kidney is very rare and has been discovered only in the adult.

Simple renal ectopia or dystopia does not begin to produce symptoms until adult life. The possibility of its occurrence in children should however be borne in mind.

Solitary kidney. Symptoms may be pain, hematuria, pyuria, or anuria, and it is important to utilize all modern diagnostic methods so that the condition is recognized. Conservative surgery is employed, and the error of removing the solitary kidney is prevented.

Horse-shoe kidney or fused kidney. The author has seen only one child with a fused kidney. This condition is readily recognized in the plain roentgen film or pyelogram.

Renal hypoplasia. The clinical importance of this anomaly is that the small amount of renal tissue present, when bilateral, is not sufficient to sustain life. The hypoplastic kidney is more subject to infection than the normal kidney.

Double kidney and double ureter. Both of these conditions occur quite frequently and often without symptoms. Their mere presence does not indicate operation. In the presence of chronic pyuria, hydronephrotic changes in one-half of the double kidney and recurring attacks of pyelonephritis, only heminephrectomy will effect a cure. As a rule the upper and smaller half of the double kidney is the one harboring the lesion.

Polycystic kidney is rarely seen in children except at necropsy because clinical manifestations usually do not appear until adulthood.

Solitary cysts of the kidney are rare in children.

Ectopic ureteral orifice occurs more frequently in the female than in the male and is often overlooked for years. The ectopic orifice in the female may be located in the urethra, adjacent to the external urethral orifice, in the vagina, or in the uterus. In the male it may be found in the prostatic urethra, the prostate itself in the seminal vesicle or in the vas deferens. A careful history will elicit the fact that the patient is "wet all of the time, losing urine continually day and night, irrespective of the act of micturition. The diagnosis is made by finding the ectopic ureteral orifice, which, in girls, can readily be located with good exposure, proper light, and a discerning eye. As a rule the ectopic ureter drains the upper half of a double kidney. As a result of this anomaly this half of the kidney undergoes hydronephrotic atrophy and frequently is infected. The treatment is heminephrectomy.

Ureterocele. Although this condition is relatively uncommon, it is important because of its devastating effect on the kidney. Hydronephrosis is always present due to interference with drainage. When infection is superimposed, chills and fever with marked pyuria lead to a diagnosis of pyelitis and medical treatment is given for long periods of time to no avail. The diagnosis is readily made on cystoscopy or in the cystogram obtained with intravenous urography in which a large filling defect appears in the bladder shadow. In early cases the ureterocele is best treated by electrocoagulation or by resection with the resectoscope. In advanced cases with severe hydro-

nephrosis, nephrectomy of the single kidney, and heminephrectomy of the double kidney may be necessary.

Congenital stricture of the ureter. In the majority of these cases the primary lesion is not at the uterovaginal junction but at the neck of the bladder with obstruction to urination with hypertrophy of the bladder wall and a resulting compression of the intramural portion of the ureter. The treatment consists of removing the obstruction at the bladder neck.

Bladder diverticulum is usually overlooked in children because of the absence of a typical symptom complex. Practically all cases are congenital and secondary to obstruction at or in front of the bladder neck. The treatment is directed toward removal of the obstruction. Only in the case of large diverticula especially when they do not empty and infection persists is diverticulectomy necessary.

Exstrophy of the bladder. The determining factors in deciding upon operative intervention are the competency of the rectal sphincter in the individual case and whether infection has been introduced into the kidneys. The author prefers to wait until the child is 18 months or 2 years old and to transplant one ureter at a time.

Obstructions at the vesical neck. These may be of either mechanical or neurological origin. The causes may be located at the bladder neck or in front of it and may be classified as follows: (1) contractures at the internal urethral orifice (2) median bars (3) valves in the prostatic urethra (4) hypertrophy of the verumontanum (5) lesions of the central nervous system (6) lesions of the prostate and (7) extravascular lesions.

The diagnosis can be made from the history and the physical examination. It should be made early before irreversible changes have occurred in the upper urinary tract.

Contractures of the vesical neck may be due to a muscular hypertrophy or a fibrosis of the vesical neck. The obstruction is removed by transurethral resection or suprapubic cystostomy and resection.

Extravascular lesions. Retroperitoneal lesions, such as tumors both benign and malignant, may produce obstruction with hydronephrosis. As the tumor enlarges a lateral displacement of the ureter occurs.

Congenital valves of the posterior urethra. If this condition is not relieved the effects upon the upper urinary tract are devastating and irreversible. Congenital valves may be destroyed by the fulgurating electrode or the resectoscope.

Hypertrophy of the verumontanum is often undiagnosed. This condition may produce severe obstruction with a resulting bilateral hydroureter and hydronephrosis.

Lesions of the central nervous system. The common cause of neurogenic bladder disturbance in children is spina bifida, which is usually recognized in the plain roentgen film.

Lesions of the prostate. Sarcoma of the prostate may be mentioned as a rare cause of urinary obstruction in children.

Undescended testicle. An undescended testicle is generally discovered during a routine physical examination by the pediatrician. One must differentiate between a true undescended testicle and a highly retractile testicle. The author believes that true undescended and ectopic testes always require surgical treatment and that endocrine therapy should be avoided because it may result in glandular imbalance or other systemic disturbances.

Surgical tuberculosis of the kidney. Surgical renal tuberculosis can be cured when the process is limited to one kidney, and when the diagnosis is made early the prognosis is excellent. The true incidence of renal tuberculosis is much higher in childhood than the present collected data seem to indicate. One must bear in mind the possibility of renal tuberculosis in children who present persistent pyuria and relapsing pyelitis. If the diagnosis of unilateral renal tuberculosis is made from the urologic examination one should rarely resort to retrograde pyelography. Nephrectomy is the proper treatment for unilateral renal tuberculosis.

Urinary calculus is seldom seen in the young in the United States, due to better sanitation improved dietetics and better care by the pediatrician but it does occur frequently enough to warrant its serious consideration. In the very young, the symptoms of stone are abdominal pain vomiting diarrhea and convulsions. As the gastrointestinal symptoms are very prominent, the presence of urinary calculi is not suspected and they are found only on routine x ray examination. Pyuria is the major symptom of urinary stone in children. If there is hematuria accompanied by recurrent colicky pain a stone should be suspected. The pathological changes associated with the urinary calculus are the same in the child as in the adult. The diagnosis and the treatment are also the same.

Hydronephrosis. Before the era of pediatric urology most of the cases of hydronephrosis and hydroureter were not recognized and the early literature deals with cases found at autopsy. As in other urologic diseases it is imperative that early diagnosis be made so that early treatment can be instituted if irreparable damage to the kidney is to be prevented. As a rule most of these cases come to the attention of the physician after the onset of infection. Because of the presence of pyuria with chills and fever many of these cases are erroneously diagnosed as acute pyelitis or acute cystitis. Hydronephrosis and hydroureter may result from (1) obstructions in the lower urinary tract anywhere along the course of the urethra from the external meatus to and including the vesical neck, (2) obstruction at the uterovaginal junction (3) obstruction at the ureteropelvic junction (anomalous vessels are not frequently found as a cause) (4) pathologic conditions extrinsic to the urinary tract (this is rare and when found is generally associated with retroperitoneal tumors) (5) lesions of the central nervous system (spina bifida) the treatment depends upon the cause.

Tumors of the urinary tract. Bladder tumors are rare in childhood. The common tumor in infancy

and childhood is the sarcoma. Unfortunately these cases are usually seen late so that the possibility of surgery effecting a cure is exceedingly remote. Kidney tumors are almost always of the type first described by Wilms, and they are now called Wilms tumors. They are congenital in origin. Of the three constant symptoms of renal tumors in general, namely a visible or palpable tumor, hematuria, and pain, only the first is constant in malignant renal tumors of children. The abdomen swells gradually becoming asymmetrically or symmetrically global. These tumors are usually discovered late because of the absence of pain and hematuria. Differential diagnosis involves excluding other renal lesions, of which hydronephrosis is the commonest, and other retroperitoneal lesions, such as sarcoma and lipoma. In other retroperitoneal tumors the ureter as demonstrated by the shadowgraph catheter is displaced laterally. The diagnosis is based upon the presence of a palpable tumor and changes in the urogram. A plain x-ray of the chest is indicated to rule out metastases. Since the metastases are usually blood-borne, indeterminate and repeated palpation should be avoided strenuously once the diagnosis has been made.

The author prefers to combine x-ray therapy with operation. A course of deep therapy is given before operation. Although not all Wilms tumors respond, the majority show a rapid diminution in size. When the tumor no longer diminishes in size having become stationary nephrectomy is carried out at once and this is followed with a course of postoperative irradiation. This technique has resulted in a great reduction of the operative mortality which today is practically nil since the diminution in the size of the tumor makes nephrectomy a simple procedure.

FREDERICK A. LLOYD, M.D.

Ferguson, C., and Hershey T. S.: Streptomycin in Urogenital Infections. *J Urol Balt* 947 57 932.

The authors studied the results of streptomycin therapy in 44 cases of urinary tract infection 42 of which were produced by gram negative organisms.

Urine was obtained from these patients by thoroughly cleansing the meatus with 1-4000 mercuric alkali cyanide. The patient was instructed to start voiding. After several ounces were passed, the sterile container was unplugged and the urine was obtained in this manner for culture. This method was found to be more practical than the passage of a rubber catheter as it is believed the catheter and lubricating jelly offer more opportunity for contamination than the above method.

The first individuals were treated with relatively small amounts of the drug at 3 hour intervals. This method was later changed to a more intensive therapy at 2 hour intervals, and larger amounts of the drug. At the present time the authors are employing 0.2 gm. intramuscularly at 2 hour intervals. They are of the opinion that not less than 5 gm. of the drug should be given in ordinary infections and that those of a severe nature should receive at least 10 gm. Their findings confirm the experience of others that where a local condition exists such as obstruction in the urinary tract or calculi which have not been removed the infection may be cleared by streptomycin. It is, however, prone to recur unless the predisposing factors are removed.

The urinary infections studied on the whole responded favorably to treatment with streptomycin.

The drug appears to be largely excreted through the urine. A good concentration is obtained in the urinary tract.

An excellent table of the 44 cases treated is appended, in which the diagnosis, the results of cultures before and after treatment, associated local pathology, the immediate and total dosage and the results of treatment are listed. An interesting observation to be made from a study of this table is in regard to the response of *Bacillus pyocyaneus* infections to streptomycin therapy. In 18 cases in which this organism was present in pure culture or in a mixed infection, it was eliminated in 11 by a total dosage of the antibiotic, varying from 2 to 10 gm. In all 3 such cases in which 10 gm. were employed the organism was eliminated.

FREDERICK A. LLOYD, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS ETC.

Langenakiöld A.: Normal and Pathologic Bone Growth in the Light of the Development of Cartilaginous Foci in Chondrodysplasia. *Acta chir. scand.* 1947 95 367

Under the name of chondrodysplasia, the author includes enchondromatosis and multiple exostosis. A combination of the latter 2 diseases is also referred to as Ollier's disease in English and American textbooks.

Röntgenologic studies of Ollier's disease reveals a bony defect either at or near the epiphyseal plate, which grows parallel with the longitudinal trabeculae and appears as if long chips of bone had been surgically gouged out. Histogenetically these foci represent a disturbance between the epiphyseal plate and the periosteum. Persistence of undifferentiated cartilaginous cells when they migrate toward the diaphysis of the long bones from the fibrocartilaginous epiphyseal plate constitutes non-ossified foci in Ollier's disease. In the main the foci retain their chondrogenic properties instead of merging into the osteogenic layer of the periosteum.

The article illustrates roentgenograms of a child 3½ years of age whose case was followed up for 2½ years. The bones exhibiting the characteristic lesions were both ends of the left femur, the lower end of the right femur, both ends of the right fibula and tibia, and the upper half of the left humerus respectively.

On the pathogenesis of multiple cartilaginous exostoses the author quotes several writers, one of whom states that the arrest in the extension of the periosteal ring permits the cartilage of the diaphyseal disc to become exposed on the surface of the shaft and thus leaves it uncovered and free to give rise to irregular outgrowths or exostoses.

His own opinion, however, is that there is a disturbance in the differentiation of a limited portion of the undifferentiated connective tissue within the epiphyseal cartilage. Due to failure of this tissue to pursue the laws of normal differentiation, growth and resorption of exostoses will invariably ensue.

Enchondromatosis differs from Ollier's disease in that it may originate from the epiphyseal plate as well as from the periphery of the metaphysis. Outside of this minute discrepancy the pathogenesis of the two diseases is quite similar.

Achondroplasia can be elucidated by a periosteal streak which develops in the epiphyseal plate of which the connective tissue layer is saturated with dynamic osteoblastic potentialities. In brief bone formation ensues in the epiphyseal plate and hence displaces the basic connective tissue (for the continuity of chondrogenic activity) and substitutes premature bone.

SAMUEL L. GOVERNALZ, M.D.

Fairbank, Sir Thomas: Dysplasia Epiphysealis Multiplex. *Brit. J. Surg.* 1947 34 225

Fairbank reports a condition which he regards as a clinical entity. The chief characteristics are dwarfism, stubby digits, and mottling or irregularity in density and outline of several of the developing epiphyses.

With regard to the differential diagnosis there are at least 7 other conditions besides osteochondritis in which the epiphyses may show irregular ossification. Cretinism is the first general condition to be excluded. The fingers are thick and stubby but fail to show their usual differences in length. Delay in fusion at the epiphyseal line in cretinism is associated with sclerosis of the terminal layer of the metaphysis.

In dysplasia epiphysealis punctata (as it is now called) or stippled epiphyses, the whole of an epiphysis seems to be ossifying in a large number of discrete centers. The shafts of the long bones are short and thick, and the ends may be enlarged and splayed. The abnormalities generally are much more gross than in most cases of the multiplex group, and no difficulty should be experienced in differentiating the 2 conditions. Congenital cataract occurs in about half of the cases.

In chondro-osteodystrophy of the Morquio-Brailsford type, but not in gargoylism as a rule, the femoral heads show striking epiphyseal changes, but in this condition the acetabula are markedly enlarged and irregular. Other epiphyses and the carpal and tarsal bones frequently show irregularity in ossification, but notable features are the abrupt kyphotic deformity in the dorsolumbar region, resulting from the diminution in size of one vertebral body which is displaced backward, and the shape of the vertebral bodies in the latter the central prolongation anteriorly is quite distinctive and diagnostic.

In dyschondroplasia, changes in the epiphyses when seen are of no importance, as these are completely overshadowed by the gross abnormality of the metaphyses. They are usually, but not invariably, unilateral in distribution. In that skeletal curiosity called osteopolkiosis, the epiphyses are of normal shape and whether fused to the shaft or not show large numbers of the characteristic discrete dense spots, although these are by no means confined to the epiphyses. In osteopetrosis or marble bones, some of the epiphyses may show irregular density or stippling, but the changes in the shafts dominate the picture.

Lastly mottled epiphyses have been described in association with pituitary gigantism (Traub 1939). Some mottling, particularly of the femoral heads, has been observed very occasionally in other endocrine disturbances and in cases which at present cannot be classified.

The author made a study of the characteristics of this condition found in 20 cases. The essential features

tures are as follows. It is an affection of children and young people—the ages varying from 6 to over 40 years. One of the cases first seen when the patient was 14 years of age has been followed for over 20 years. Both sexes (12 males, 8 females) are affected and, as a rule, the condition is not inherited or familial. Intelligence is usually normal. In 8 of the cases difficulty in walking was complained of while in at least 5 others pain and stiffness of the knees or hips was the trouble which caused the patients to enter the hospital. Some degree of dwarfism, of the short limb type, is the rule. It being definitely recorded in 16 of the cases. The facies typical of cretinism is absent. Some enlargement of the epiphyses is occasionally seen. The hands are striking, the fingers and thumbs being short, thick, and stubby with blunt ends, but the relative length of the digits being normal. Apart from the dwarfism and the shape of the hands, there is no characteristic deformity but flexion deformity of the knees was found in 3 cases with subluxation in 1 case. In 1 case the elbows were flexed and laxity of the wrists and knees was present. In another a curious deformity of the elbows was seen, the radial heads being subluxated. In yet another there was limitation of abduction of the shoulders and of extension of the elbows while the knees were flexed and the tibial heads subluxated backward. Genu valgum was present in 4 cases, and dislocation of the patella, and bowlegs in 1 case each.

The roentgenological findings indicate that the epiphyses may be late in appearing and backward in development, and fusion with the shafts may be delayed, but the principal change is irregularity in ossification. The epiphyses are irregular both in density and shape, being mottled in appearance and perhaps mulberrylike in outline. Separate subsidiary centers around the main center are common, and this results in some peripheral stippling but this is never carried to the point seen in the punctate type of epiphyseal dysplasia. Eventually the epiphyses become normal in density but the outline, though usually smooth, remains permanently abnormal. Any or all of the epiphyses may be affected but the most common to show typical changes and permanent deformity are the hips, shoulders, ankles, and, less frequently the knees. The heads of the femora (and of the humeri) remain permanently shallow and less convex than the normal.

The ankles show marked obliquity of the joint in the condition under discussion.

The author suggests that if there is reason to suspect pseudotumors in a patient below the average in height it is well worth while to have films taken of the shoulders and ankle to exclude the developmental error which is the subject of this article.

C. FRED GORRINGER, M.D.

Rocher, H. L.: Pseudo-tumeurs; Léri's Disease. (La pseudo-tumeur. Maladie de Léri) *Rev. orthop. Par.* 1917 33 34.

Léri's disease is a congenital osseous dystrophy characterized by premature and excessive develop-

ment of the epiphyses of the bones of the extremities. The excessive enlargement of the epiphyses causes stiffness of the adjacent joint. The diaphyses are short and hypertrophied. Some epiphyses in the same individual may be underdeveloped. The endochondral ossification of the epiphyseal plates is deranged and results in either hyperplasia or hypoplasia.

Two more cases of this rare disease are added to 2 cases previously reported by the author. A 6 year old boy born to consanguineous parents was brought for examination because of multiple deformities. His birth had been normal, he walked at the age of 17 months, and talked at the age of 1 year. In addition to the joint deformities, there was an umbilical hernia and a left inguinal hernia. The head was large and the root of the nose depressed there was a dehiscence frontoparietal suture, enlargement of the sella turcica, strabismus, and slight lumbar kyphosis. The corneas were turbid. The joints of the upper extremities were thick, not painful, but showed limited range of motion. The hand was pawshaped and the fingers were kept in slight flexion with extension limited to 10 degrees. The x ray examination showed a large humeral epiphysis. The diaphyses of the humerus, radius, and ulna, and the metacarpals and phalanges were short and thick. The ossification centers of the carpus were present but small. The ossification center of the distal end of the radius was absent. There was coxa valga without enlargement of the upper end of the femur. The knees were large and their motion was limited to 160 degrees. The ossification center of the upper tibia showed deficiency in its development.

The second patient showed similar findings.

The changes found in Léri's disease could be classified as achondroplasia. The stiffness of the joints, however, which is never observed in achondroplasia, makes Léri's disease a separate entity. The hands, for example, are shaped similarly as the hands observed in achondroplasia. In Léri's disease the joints of the hand are stiff and the range of motion is considerably reduced.

The lack of transparency of the cornea suggests a pathogenic relationship between the ill developed corneal mesenchyme and the irregularly developed preosseous mesenchyme. Heredity did not play any part in the cases presented by the author.

There is nothing known as to the etiology of this condition. In view of the deformed pituitary fossa, a deficiency of the pituitary gland might be an etiological factor. GROVER L. RIME, M.D.

Platt, Harry: Sarcoma in Abnormal Bones. *Brit. J. Surg.* 1947 34 3.

The author discusses 180 fully documented primary malignant tumors of bone 161 of which belonged to the sarcoma group and 18 of these were sarcomas occurring in abnormal bones. This subgroup contained (1) 10 sarcomas occurring in Paget's disease (2) 2 sarcomas arising in fibrocystic disease

and (3) 6 tumors representing the malignant transformation of a previously benign osteochondroma.

The incidence of sarcoma in osteodystrophias deformans has been estimated by various observers as between 5 and 10 per cent. In the present series 8 of the patients were males and 2 females. The malignant tumors appeared in 4 patients between the ages of 50 and 60, and in 6 patients over 60. Four tumors involved the femur (lower end, 3 upper end and shaft, 2) and 3, the pelvis (ilium, 2 pubis, 1). In the majority of the cases there was a fairly long prodromal stage in which Paget's disease was present either in one bone or throughout a considerable tumor. The histologic type of tumor in all cases was a spindle or polymorphic sarcoma.

The prognosis in the sarcomas in Paget's disease would appear to be grave. In 7 of 10 cases in the series the patients died within a year from the discovery of the tumor and its treatment. One patient has so far survived 3 years from the time of amputation. The appearance of sarcoma in an area of fibrocystic disease is a rare phenomenon. In the 2 recalcitrant cases the survival periods were 2 years and 9 years respectively. In the former there was an inoperable tumor of the pelvis of gigantic size. At the time of death no evidence of metastasis was revealed. Because of his experience with these 3 rare cases the author concludes that it is best to obliterate cysts in adults by appropriate operative procedures (curettage and the implantation of bone grafts). In the type of sarcoma resulting from the malignant transformation of an osteochondroma (6 cases in the series) examples of long survival periods are likely to be encountered. Although rapid growth and the attainment of enormous size are not in themselves conclusive evidence of the advent of malignant change such tumors should be eradicated without delay.

C. FRED GORRIKOW, M.D.

Bennett, Granville A.: Malignant Neoplasms Originating in Synovial Tissues (Synoviosarcomas). A Study of 32 Specimens Registered at the Army Institute of Pathology during the War time Period from 1941 to 1945. *J Bone Surg* 1947 29: 259.

During the years of the recent war a large number of neoplasms and neoplastidlike lesions, originating in joints, bursae tendons and tendon sheaths, were submitted to the Army Institute of Pathology for interpretation and classification. A review of this material has demonstrated that 32 specimens conformed in their cytological and structural features to the malignant neoplasm of synovial membrane origin. An illustrated descriptive analysis of these lesions together with a tabulation of essential clinical information forms the basis of this report, which is presented for the purpose of familiarizing both surgeons and pathologists with this important group of sarcomas.

The remaining lesions of synovial origin included numerous examples of the giant cell tumor of the tendon sheaths and joints, pigmented villonodular synovitis, and xanthomatous tumors of the joints. A few representative lesions are illustrated in order to permit a comparison of their microscopic appearances with those of the malignant tumors. Such a comparison would seem appropriate since it has become evident that it is not always easy to distinguish between benign tumorous overgrowths and malignant neoplasms.

There is historical evidence suggesting that in some instances at least, a malignant tumor (synoviosarcoma) may develop in or near a joint or some other synovial lined structure that has been swollen or otherwise abnormal for many months or years. It is quite analagous all patients from whom benign neoplasms or other tumorlike lesions of synovial tissues have been removed. Such a study of the vast amount of material now registered with the Army Institute of Pathology should give more precise information as to whether benign lesions may acquire malignant qualities as well as provide histological criteria which would sharply delineate between the innocent lesions and those that are potentially dangerous.

The usual treatment employed in this series was local excision followed in many instances by wider excision or amputation at a considerably later date. Thus it is essentially similar to that reported in previous studies in which the fatality rate from metastases was exceedingly high.

Because of the demobilization procedures it has not been possible to obtain recent follow-up information in many of the cases of the present series. No progress notes have been obtained from 8 patients. It is known however that 11 of the patients died with widespread metastases. In 3 additional patients metastases are known to be present, and in 3 others recurrences have been reported. This points to the seriousness of this neoplasm and emphasizes the necessity for its prompt and complete removal.

If the present discouraging death rate is to be lowered there must be closer co-operation between the surgeon and the pathologist. The pathologist must develop skills and techniques which will enable him to interpret these lesions properly and the surgeon must take the necessary means to eradicate the local lesions without resorting to preliminary conservative measures.

RODOLPH S. REICHER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

De Anquin, Carlos E.: Morsmosen a Osteotomy as a Palliative Operation on the Hip (La osteotomía de Morsmosen entre las operaciones paliativas de la cadera). *Rev orlop traumol.* B. Air., 1946 16: 21.

Because of the destructive character of congenital hip lesions total reconstruction is impossible.

Fig. (De Auzay). The excellent results from Mommsen's osteotomy.

Hence only palliative intervention is indicated. Kirrmisson in 1892 utilized a subtrochanteric oblique osteotomy for the correction of this lesion. Lorenz and Baeyer simultaneously proposed bissection of the femur and anchorage of the superior fragment by utilization of the pelvitrochanteric muscles. The lower section of this femur was placed in 45 degree abduction and in from 5 to 20 degrees of hyperextension. With this procedure they created a Y-shaped femur. Schanz bisects the femur at the level of the ischium using this structure for support of the femur.

The bad features of each repair are discussed and the author believes that Mommsen's method satisfactorily overcomes these. He describes the technique in detail. A 3 cm. incision is made over the external part of the femur so that the part to be resected is at the level of the ischium. This is determined with x-ray views. The femur is transected from without in as far as the medulla and again outward from within several centimeters lower.

The 2 parallel cuts are joined by a perpendicular one. The lower part of the femur is now abducted, and a body cast which incorporates the leg is applied and left in place for from 30 to 40 weeks.

A case report is presented. The accompanying illustration shows the excellent end results.

STEPHEN A. ZICKMAN, M.D.

Wilson, Phillip D.: Trochanteric Arthroplasty in the Treatment of Ununited Fractures of the Neck of the Femur. *J Bone Surg* 1947 29: 3-3.

The term "trochanteric arthroplasty" is used in this article to designate an operation on the hip, in which the head and neck of the femur are removed and the trochanteric end of the shaft of the femur is reshaped, covered with a vitallium cup or mold and then placed in the acetabulum. As a preliminary step the tip of the greater trochanter is cut away from the rest of the femur, the attachments of the gluteus medius and gluteus minimus being preserved. This fragment is later transplanted to the shaft of the femur distal to the greater trochanter.

The operation is a development of the ideas of Whitman, Colonna and Smith Petersen.

The various steps of the operation are clearly shown in illustrations accompanying the article.

The hip is maintained in a position of abduction and extension for a period of from 4 to 6 weeks, generally in a plaster-of-Paris spica. The knee joint may be freed at a considerably earlier period to permit mobilization and exercises. Following removal of the plaster mobilizing exercises of the hip are started. Weight bearing is not permitted until the end of from 8 to 10 weeks, and then only with crutches.

The chief complication that must be guarded against is luxation particularly during the first 2 weeks after the plaster is removed.

A summary of 9 cases in which operation was performed by this method shows the results were excellent in 4, good in 2, cases fair in 1 case and poor in 2 cases.

The writer does not propose trochanteric arthroplasty as the proper method of treating all ununited fractures of the neck of the femur. However trochanteric arthroplasty has two advantages over the usual arthroplasty of the femoral neck. First, it eliminates the neck of the femur and for an angular thrust, it substitutes a direct vertical thrust in the axis of the femur. This simplifies the mechanics of hip function and reduces the likelihood of instability due to insufficiency of the iliofemoral muscles. Second, there is a more abundant blood supply to the trochanter than to the femoral neck, hence there is less chance of postoperative absorption of bone which is frequently a troublesome feature after arthroplasty of the femoral neck.

These advantages are sufficient to more than counterbalance the single disadvantage which is the tendency of instability of the hip in the early postoperative period and the necessity of taking certain precautions to guard against luxation. Perhaps eventually a way will be found to make these hips more stable by surgical implantation of a bone shelf.

While trochanteric arthroplasty is particularly indicated in the treatment of certain ununited fractures of the neck of the femur it is also of value in many other pathological conditions of the hip especially those accompanied by destruction of the head and neck of the femur.

RUDOLPH S. REICH, M.D.

Parker J. M. and Modlin J. J.: Compound Injuries of the Knee Joint. Study 2—The Infected Knee Joint. *Ann. Surg.*, 1947 125 385

World War II has witnessed a significant change in the surgical treatment of severely traumatized and infected knee joints. Rather than merely the saving of a limb or a life, the conservation of function has become the goal. The conclusions are based on cases seen at the Twenty first General Hospital, St. Louis Missouri (Washington University Unit) during the African, Italian and French campaigns. Established infection can be controlled and a functioning joint obtained by (1) removal of all actually or potentially devitalized tissue and foreign material which can serve as foci of infection, (2) control of the residual infection by the systemic and intra-articular use of penicillin, (3) closure of the knee joint to exclude re-infection from without and to insure retention of the penicillin, (4) the institution of early active motion.

The infected joint most amenable to the therapy outlined by the authors is the one with minimal fracture rather than one with extensive fractures and soft tissue loss. A total of 244 penetrating and perforating wounds of the knee joint were treated. Clinical infections developed in 29 of these. The infections are classified as acute, subacute and chronic, the latter being most subtle and most likely to escape diagnosis.

The gross pathology of the different stages is described. Attention is called to the menisci which early appear viable but in later stages degenerative signs such as dullness, softening, and yellow discoloration are frequently noted. In the chronically suppurating joint, menisci are generally found to be degenerated, erosion of opposing cartilaginous surfaces is present, and the joint cavity is partially obliterated by adhesions.

By arthrotomy and by observing the criteria mentioned herein, the authors believe that definite advantages were gained over prior methods of drainage and immobilization. Of the 15 patients selected for this method of treatment, 14 were considered to have had a successful result from the standpoint of arrestment of the infection and preservation of a serviceable knee joint.

Although basic tenets were débridement including excision of the menisci, closure of the joint, and institution of penicillin, the extent of débridement varied in the different stages of the infected knee. In the acute septic knee, menisci were removed by medial and lateral parapatellar incisions despite appearances because of known low vitality and susceptibility to infection as indicated from the study of knees in the later stages. In the subacute stage, the meniscus on the side of the injury was removed and decision as to removal of the opposite meniscus was made upon examination at surgery. With developing chronicity, good functional results are less frequent. Usually both menisci are found to be degenerated and areas of necrotic cartilage are present. In such cases, the menisci are removed and devitalized cartilage is curetted to good bone. If the procedure is too

extensive to expect minimal joint function, resection of the joint may be performed.

Both menisci were removed in 8 of the 15 patients; the lateral meniscus alone was removed in 5 and the medial meniscus was excised in 2 patients.

The remaining 14 infected knees in the series of 29 cases were considered too extensive to be amenable to arthrotomy and débridement. Four of these knee joints were resected to control infection. One of the patients in whom resection was done required subsequent amputation to control fulminating osteomyelitis.

KENETH H. SPORNEL, M.D.

FRACTURES AND DISLOCATIONS

Stark, W. J.: The Value of External Skeletal Fixation in Elective Orthopedic Surgery. *Ann. Surg.* 1947 125 372

The Roger Anderson apparatus has been used frequently for the treatment of fresh fractures, but the present study comprises 57 elective orthopedic procedures in which it was used (bone grafting to old

Fig. 1 (Stark). a, Roentgenographic appearance of knee joint to months following a compound fracture of the tibia (gunshot wound) involving the knee joint originally with osteomyelitis and septic arthritis. b, Anteroposterior view of a surgical arthrodesis of the knee joint 10 weeks post-operatively. Early union is present. Immobilization discontinued in 14 weeks, when ankylosis was complete. Four $\frac{1}{2}$ inch pins are used and their position is clearly indicated in the roentgenogram. The two oblique pins cross through the knee joint. The articular cartilage is removed from opposing joint surfaces before these oblique pins are inserted.

Fig. (Stark) a. Roentgenograms of compound fracture of the tibia 10 months following gunshot wound. There had been continuous immobilization since this patient was wounded, including 3 months in a walking plaster. The skin wound had been healed for 8 months. b. Roentgenographic appearance 12 weeks after a sliding bone graft with additional cancellous bone from the opposite tibia. Immobilization discontinued in 16 weeks with union present. c. Photograph of the patient after surgery.

nonunions, arthrodeses, and humeral shortenings). The bone grafts were all full-thickness onlay or inlay grafts, all cancellous grafts being reported separately.

The appropriate size of pin is used for each bone or joint, from a $\frac{1}{16}$ inch pin for the tibia and femur, to a $\frac{1}{8}$ inch pin for the wrist joint. Pins are inserted by a slow speed hand drill to eliminate thermal damage to tissue. Anatomically correct sites must be chosen for the insertion of pins to avoid pin seepage. Pins are inserted before the operative incision is made. In the femur and tibia, through and through pins are used with the half-pin units. After exposure of the site the desired position is secured and maintained by locking the clamps. Application of a graft is then simple. Sterile gauze is secured about the pins and changed infrequently; plaster dressings are not used. Most of the lesions in the author's series were old gunshot wounds, many of which had been infected. Periods of fixation ranged from 30 weeks for the average bone graft to the femur to 12 weeks for a graft to the radius. Similarly the average fixation period for arthrodeses was 30 weeks for an elbow to 12 weeks for a wrist.

A representative group of cases is presented together with photographs and before and after roentgenograms showing the apparatus in situ after union had taken place. Pin seepage occurred in 21 per cent

of the cases. It is differentiated from infection about the pins which did not occur in this series, and is due to movement of the soft tissues around the pin. All pin tracts were healed in from 7 to 15 days. No sequestra or osteomyelitis occurred at pin sites. There were 2 cases of delayed union. In 4 cases there was exacerbation of infection in the old compound wound which healed again in from 3 to 8 weeks without involvement of the operative site. Infection of the surgical wound occurred in a mental patient but eventually cleared the graft remaining in place. No renal calculi were present in the group.

The advantages of external skeletal fixation are: (1) continuous rigid fixation of the fracture site, (2) simplification of the operative procedure and elimination of the need for plaster casts, (3) early active mobilization of the adjacent joints, (4) early ambulation is permitted (8 to 10 weeks of weight bearing with pins in place), (5) a minimum of nursing care is required and patients are reasonably comfortable. The disadvantages are the dangers of complications as noted above.

FRANCIS E. BRIDGECR, M.D.

Allaria, A.: Fracture of the Acromion (*La fratture dell'acromion*). *Chir. org. novim.*, 1945, 30: 425.

In the author's material of 13,860 fractures there were 133 fractures of the scapula (0.95% of all cases). Fracture of the acromion was diagnosed in 18 cases.

Lecture. He has selected as his subject "The Qualifications of the Surgeon and the Cancer Problem."

CONVOCATION

The Convocation will be held on Friday evening in the Grand Ballroom. It will open with a presentation of officers, regents, governors, and initiates. The new President Dr. Arthur W. Allen will preside and will confer the fellowships and the honorary fellowships. Dr. Irma Weil, Past President and Chairman of the Board of Regents, will present the candidates for fellow ship.

GENERAL SURGERY

In general surgery the program at the head quarters hotel will embrace three evening symposia and seven afternoon panel discussions, all on very timely themes.

The Tuesday evening symposium will be on "The Proper Use of Blood and Blood Plasma" with the following subjects and speakers: "A Permanent Red Cross Transfusion Service," G. Ford McGinnis, Washington, D. C. "Blood Bank Organization," Paul L. Hoxworth, Clinch

and Reactions to Blood Transfusion and the Rh Factor," Louis K. Diamond, Boston. "The Use of Blood and Plasma in Surgery," Dallas B. Fletcher, Chicago.

The Wednesday evening symposium will be on "Nutritional Requirements in Surgery" with the following subjects and speakers: "Proper Employment of Oral Feeding" (speaker to be announced), Parenteral Feeding (including use of amino acids and glucose), Robert E. Mann, St. Louis. "The Importance of Adequate Supply of Blood and

Nourishment for Wound Healing," Champ Lyons, New Orleans.

The Thursday evening symposium will be on "Hypertension with the following subjects and speakers: "Fundamental Physiological Considerations for Surgery in the Treatment of Hypertension," Thomas P. Findley, New Orleans. "Surgical Procedures in the Treatment of Hypertension," Reginald H. Smithwick, Boston. End Results in the Treatment of Hypertension," (speaker to be announced).

The following subjects have been chosen for the afternoon panel discussions in general surgery. Participants are shown in so far as accepted. had been received at the time copy for this issue was prepared.

Pulmonary Suppuration—Monday 1 to 3:30 p.m. Leader, Everett A. Graham, St. Louis.

Collaborator: Brian Black, Washington, D. C. Pancreatitis—Monday 3 to 5:30 p.m. Leader, Miss Garg, New Orleans. Collaborator: John McLaughlin, Rochester, Minnesota. Hirschowitz, San Francisco. Surgery of the Hand—Tuesday 1 to 3:30 p.m. Leader, Henry C. Marble, Boston. Collaborator: Henry S. Allen, Chicago, L. H. McKim, Montreal, and J. Harold C. Smith, Toronto. Jointure—Tuesday 3 to 5:30 p.m. Leader, Charles B. Fournier, Chicago. Collaborator: L. S. Ravdin, Philadelphia. James T. Fitzhugh, Rochester, Minnesota. Gastric Surgery—Wednesday 1 to 3:30 p.m. Leader, Howard K. Gray, Rochester. Use of Antibiotic Agents and Chemotherapy in Surgery—Wednesday 1 to 3:30 p.m. Leader, John S. Lockwood, New York. Collaborator: C. Phillip Miller, Chicago. Frank L. McKinney, New York. Harold V. Daniel, Philadelphia. Edwin J. Pajdak, Fort Sam Houston, Texas. Late Results of Compound Craniocerebral In Jures—Thursday September 11 3 to 5:30 p.m. Leader, J. Earl Walker, Chicago. Collaborator: James C. White, Boston, and Cobb, Pulchert, Nashville.

OPHTHALMOLOGY

An exceptionally interesting program is being planned for ophthalmologists, consisting of two evening symposia, three morning panel discussions from 9:30 to 10, and an evening session on Wednesday in which a combined program with the ophthalmology symposia will be held. Subjects for the Tuesday evening symposium will be "Epithelial Downgrowth Following Cataract Operation," Local Treatments in Ophthalmology, "Operative Treatment of Vertical Tropia," "Amblyopia—Treatment and Treatment of Postoperative Complication of Cataract Extraction." Subjects for the Thursday evening symposium will be Surgical Physiology of the Eye. Muscles—With Special Reference to Squint. Glaucoma following Cataract Extraction. Retinal Detachment. "The Difficult Cataract Extraction. Subjects for the morning panel discussions will be Tuesday—Surgery of Extracapsular Muscles Wednesday—Surgery of Glaucoma Thursday—Angiographic Ocular Lesions. Subjects for the Wednesday evening combined session on ophthalmology—Ophthalmology will be Blood Supply of Eye and Sinuses. "The Cryosurgery in Eye Surgery in Eye Diseases, Ophthalmoneurological Symptoms in Nasopharyngeal Tumors.

(13.23% of all fractures of the scapula, or 1.29 per 1,000 of the entire fracture material)

The differential diagnosis should consider (1) so-called acromial bone, or "Ridge's bone" resulting from a deficient process of ossification, and (2) scapular bone, namely the acromial and/or secondary

As to the mechanism of the fracture, direct trauma was responsible for 72.7 per cent of the fractures of the acromion, while indirect trauma to the elbow or the forearm was responsible for the remaining cases.

Inspection of the shoulder from the back reveals characteristic ecchymoses in the acromial region are present. Palpation is painful and inspiration frequently provokes pain but the functional examination may fail to furnish distinct results. From the anatomopathologic and roentgenographic point of view fractures of the acromion may be divided into three groups (1) fractures of the distal extremity (2) fractures of the articular or acromioclavicular portion and (3) fractures of the base of the bone. The first two types are relatively rare.

As to therapy bandaging of the arm to the trunk is sufficient if the fragments are in good apposition. Otherwise immobilization of the arm in the position of abduction and intermediate rotation with the elbow flexed to 90 degrees is suggested by the author. If the fracture is combined with a dislocation, the latter should be reduced first. In exceptional cases introduction of a wire and the application of traction or an open reduction may be required.

JOSEPH K. NARAT M.D.

Piqué, José Alberto: Treatment of Old and Painful Bilateral Congenital Dislocation of the Hip
(A propósito del tratamiento de la luxación congénita bilateral inveterada y dolorosa de la cadera)
Rev. ortop. traumat., B. Air 1946 16 65

Any treatment for old congenital dislocation of the hip should take into account regional anatomy the type of luxation the mechanical changes which occurred during the early stages and the presenting acute symptoms. There are two main types of congenital dislocation of the hip (1) the anterior or supra-acetabulum dislocation which has 5 subtypes and (2) the posteroinferior which has 3 subtypes the intermediary and the high.

The regional anatomical changes, together with a series of disturbances which are conditioned by 4 factors (a) insufficient or absence of femoral stability (b) bad orientation of the bony parts (c) shortening disproportion of the extremities and (d) displacement of muscular insertions while walking. The clinical symptoms are pain, fatigue on walking, slowing of gait, and defective posture.

Certain cases of old dislocations are not amenable to surgical treatment and nonsurgical procedures should always be tried before resort is made to any open method. These include rest, and the use of orthopedic appliances, medicine, and physical ther-

apy. Surgical treatment employs palliative and definitive methods. Palliative treatment is divided into intra articular extra articular and complementary operations. The intra articular operations include resection of the head of the femur pseudarthrosis of the femoral neck, and arthrodesis.

The extra articular operations are the various osteotomies aimed directly at correction of the adduction or correction of the flexions on the one hand and those for the purpose of stabilizing the pelvis, such as the Lorenz bifurcation method, or the Schanz ischial attachment and their modifications.

The complementary operations are designed for the correction of the inequality of the extremities by lengthening the short member or shortening the longer one or by harnessing the fragments.

STEPHEN A. ZIEGLER M.D.

Leveuf J. and Pals, G.: Congenital Dislocations of the Knee (Les dislocations congénitales du genou)
Rev. arthrop. Par 1946 33 313.

The authors differentiate between 3 varieties of anterior displacement of the knee
1 Congenital genu recurvatum, in which the articular surface of the tibia glides anteriorly on the femur but the contact of the articulating surfaces of the tibia and femur remains preserved

Fig. 1 (Leveuf) Bilateral subluxation of the knee. The radiogram of the left knee shows the partial loss of contact between the articular surfaces and the overriding of the cartilaginous epiphyses.

Fig. 3 (Levent) Subluxation of the right and luxation of the left knee. Luxation of the left hip. Anterior and external overriding of the tibia and hypoplasia of the epiphyseal ossification center of the metaphyses and diaphyses of the left femur

2 Congenital subluxation in which the posterior part of the tibial epiphysis articulates with the anterior surface of the trochlea of the femur. The tibial epiphysis is displaced anterior to the epiphysis of the femur

Fig. 4 Arthrogram showing subluxation of the right side during hyperextension and luxation of the left side with marked overriding and interposition of the subpatellar synovial membrane and hypoplasia of the capsule.

Fig. 5 Arthrogram of the left genu recurvatum with tibia in hyperextension hypoplasia of the capsule and cartilaginous deformation of the tibial epiphysis in the form of donkey back.

Fig. 5 Arthrogram of subluxation of the left knee. Overriding of the cartilaginous epiphyses which are hypoplastic. Articular cavity decreased. Convexity of the tibial epiphysis displaced superiorly and anteriorly even during attempts of reduction (last picture).

3 Complete congenital luxation in which no contact exists between the articular surfaces of the two bones. The tibia is dislocated not only anterior but also lateral to the femur

Since the epiphyses are cartilaginous and transparent to the x-rays in the newborn, simple roentgenography gives only an incomplete picture of them and of the degree of subluxation or luxation. Arthrography (filling of the glenoid cavity with a contrast medium) permits visualization of the contours of the epiphyses of the whole extent of the joint cavity with its recesses (subglenoid, subacromial and popliteal) and of the soft tissues inside the joint (anterior adipose pad, menisci, thickening of the synovium).

There is atrophy and deformation of the epiphyses of the femur and tibia. The quadriceps muscle is atrophic and shortened. In many cases the patella is atrophied and in some cases it is missing. Microscopically the muscles present fatty infiltration, thickening of the perimysium and some times cloudy swelling.

Little is known about the etiology and pathogenesis of this malformation. Just as congenital dislocation of the hip joint, congenital dislocation in girls than in boys. About 60 per cent of the cases in the literature showed other malformations besides dislocation of the knee. Most frequent among these were luxations of the hip and in 10 per cent pes equinovarus was present. Other cases showed spina bifida, anal atresia, hardlip and strabismus.

In genu recurvatum it is sufficient to immobilize the knee in a cast for 2 or 3 months. Subluxation and luxation require either orthopedic reduction or surgery. Orthopedic reduction should be done only under roentgenoscopic control, immediately after the arthrogram has been taken. In attempting to reduce the luxation, one has to proceed very gently as the danger of separation of the epiphysis is great. In surgical reduction, the most important step is the lengthening of the extensor apparatus, either by a simple Z-formed incision of the quadriceps tendon or if the shortening of the quadriceps is very marked by more complicated techniques which are discussed in detail. In addition, in cases of luxation it is necessary to open the capsule and to remove the hypertrophic tissue of the synovial membrane between the patella and the tibia.

The authors discuss 5 cases observed by them
WERNER M. SOLMIZ M.D.

ORTHOPEDICS IN GENERAL

Cheyne, J.: A Study of the Pathology of the Hip Joint (Recherches sur la physio-pathologie de la hanche) *Rev. orthop.* Par 1947 33 7

Examination of the round ligament in 50 autopsies demonstrated its variation as to length and size. A round ligament however was found in every hip joint. An opaque substance was injected into the iliac artery of fresh adult children and new-

Fig. 1 (Cheyne) The femoral head in the newborn.

born cadavers and the hip joint was then x-rayed. A histologic examination was also made of every round ligament.

In the newborn a number of arterioles were found to be located at the periphery of the round ligament. These vessels however do not penetrate into the still cartilaginous femoral head. In the adult, several (about 5) arteries were found to traverse the round ligament in its entire length, converge and penetrate into the osseous portion of the femoral head. In the aged the round ligament showed very poor vascularization. The roentgenograms of the specimens supported the histologic findings. In the adult a definite anastomosis existed between the vessels of the round ligament and the anterior and posterior circumflex vessels. There were a few neurofibrils at the periphery of the round ligament which obviously were of little clinical significance.

The femoral head gets its blood supply from 3 sources: the obturator artery through its arterioles within the round ligament, and the anterior and posterior circumflex arteries. In the newborn the anterior circumflex artery fails to supply branches to the femoral head. The posterior circumflex artery before penetrating the femoral head follows a spiral course around the posterior aspect of the head (Fig. 1).

Fig. 2. The paucity of the intrinsic circulation in an individual 70 years of age.

The posterior circumflex artery gives off branches along its course. It never communicates with the round ligament vessels in the newborn. Thus, an avascular area is formed in the superior medial corner of the femoral head which is the exact site where the ossification center seems to appear at the age of 16 to 18 months. In the adolescent, anastomosis between the 3 systems seems to increase more and more (beginning between the ages of 10 and 12 years). In the adult definite and extensive communication between the 3 vascular systems is established.

The anterior circumflex artery gives off a recurrent nutrient branch (Nussbaum) which enters the femoral neck to anastomose with branches of the posterior circumflex artery. The posterior circumflex artery gives off 3 sets of branches: (a) at the inferior border of the femoral neck, i. e. inferior nutrient vessels of the head and neck (Lexter Waldenstrom); (b) branches that enter the posterior aspect of the neck; and (c) superior branches which clinically are the most important. One branch is a recurrent trochanteric branch, and 3 large branches enter the head and neck. The arterioles of the round ligament communicate with the superior and inferior nutrient arteries of the posterior circumflex artery. In the adult there is no avascular zone in the femoral head. In the aged, roentgenograms of the injected specimens clearly show the paucity of the intrasosseous arteries of the femoral head, and the lack of anastomosis of the round ligament arteries with the other vascular systems (Fig. 3).

Osteochondritis dissecans of the femoral head (König's disease) in which a small superficial osteo-cartilaginous sequestrum is formed is caused by a disturbance of the vessels of the round ligament, i. e. endarteritis obliterans, embolism, or spasm. A similar vasomotor process is most likely responsible for similar conditions in other joints, for example, the shoulder elbow and knee.

A similar process causes Legg-Calve's disease in the hip joint. Anastomosis of the vascular system of the round ligament and the posterior circumflex artery is not established before the age of 10 or 12. It is possible that vasomotor disturbances of the round ligament arteries are responsible for these changes.

GEORGE I. RENN, M.D.

Wilkinson, W. R.: Coccygodynia; Review of the Literature and Presentation of Cases. *South. Surgeon*, 947 3 280.

Coccygodynia means painful coccyx, but the term refers to a clinical entity which may include other symptoms. This condition may well be called pelvic myoneuralgia.

To understand the relationship of the lesion to the symptoms, the anatomy of the pelvis must be known. The muscles involved are the piriformis, coccygeus, and levator ani, which are components of the pelvic floor. The piriformis muscle is in close relationship in a variable manner with the sciatic and gluteal nerves. The coccygeus and levator ani have attachments on

the coccyx. The writer further expands on the extensive pelvic innervation. From the anatomic descriptions, it can readily be understood that inflammation of any of the pelvic viscera can cause spasm of those muscles mentioned here thereby giving rise to the symptoms of coccygodynia.

At the Laird Memorial Hospital, Montgomery West Virginia, 20 of the last 23 cases observed were in females. Other writers have reported corresponding ratios.

The author states that the symptoms of coccygodynia are the result of an imbalance of the pelvic musculature. Pain may be referred to the coccyx, anorectum, pelvis, or the suprapubic, lumbar and perineal regions. Many combinations, and occasionally simply coccygeal pain, may obtain. The author attributes most of the cases of coccygodynia to inflammation of the pelvic organs in both men and women. Trauma and psychogenic factors account for a small percentage of cases. It is more likely that nervous is a result, rather than a cause of coccygodynia.

The diagnosis may be suspected in any patient complaining of rectal or coccygeal pain, or any combination of the previously mentioned symptoms. The most common physical finding is a spasm of one or more of the muscles of the pelvic floor. The affected muscles have a swollen, beefy feel to the examining finger on rectal examination. Spasm of any of the subject muscles can cause the pain due to muscle imbalance. If there is severe unilateral spasm, the stool may take on a triangular shape. In prolonged, untreated cases the affected muscle will become small and feel not unlike bands of banjo strings. The examination by pressure on the affected muscle may elicit pain duplicating the patient's complaints. Local and remote foci of infection should be sought and corrected. X-rays contribute nothing to the diagnosis.

The author believes that the treatment of coccygodynia is entirely nonsurgical. There is no indication for excision of the coccyx for coccygodynia per se. The treatment is massage. This is accomplished as for a rectal examination, and the finger massages the muscle in the direction of the fibers, which causes rather severe pain at first, so gentle massage, followed by increasing pressure as the pain diminishes, is the method of choice. Too vigorous massage may cause hemorrhage into the muscles. Three treatments per week of about 2 to 3 minutes each give the best results. The number of treatments is dictated by the progress of the patient. The average number in the present series was 15.

Other aids in treatment include a sitting posture to avoid pressure on the coccyx, heat, and especially relief of constipation.

Follow-up in 8 of the last 23 patients operated upon for excision of the coccyx indicates that only 2 obtained relief. The last 22 patients were treated by massage, and 8 were relieved. Two of the 11 were advanced cases, having gone to the banjo string stage.

KENNETH H. SPOONER, M.D.

Lacroix, P.: Stimulation of the Longitudinal Growth in the Tibia by Elevation of the Diaphyseal Periosteum (Excitation de la croissance en longueur du tibia par décollement de son périoste diaphysaire) *Rev. orthop.*, Par 1947 33 3

Partial operative arrest of growth of the longer extremity for equalization of length of both extremities has been successfully used in children for some time. Many workers devised numerous procedures such as insertion of foreign bodies near the epiphyseal plate, or curettage of the marrow cavity through a window to excite increased growth in the long bone of the shorter extremity but all these attempts failed.

The author stripped the entire periosteum of the tibia in 10 rabbits. An increase of growth was observed from 0.5 to 4.5 cm. within from 20 days to 5 months. A similar observation was made by Ollier in the year 1867. However it is suggested that a great deal of further investigation is necessary before much significance can be attributed to these experiments.

It is believed that an increased blood supply alone cannot be responsible for the increased growth because lumbar sympathectomy did not cause an

increase of growth in young individuals although it caused an increased blood supply to the lower extremities.

The author suggests that venous stasis exerts a definite stimulating influence on osteogenesis. Ligation of the large veins in the extremities accelerates callus formation (Pcasso and Morton McMaster Roome). The increase of reparative osteogenesis would however not explain the increase in length of the long bones. Bergman and Kishikawa stated that venous stasis has no definite influence on the epiphyseal plate.

The author has recently demonstrated that there are organic substances which act on the enchondral ossification of the epiphysis. It is possible that by stripping of the periosteum an increased amount of this substance is liberated. It is further assumed by the author that the osteogenic powers of the periosteum are stimulated by the same substances that act on the epiphyseal plate. This hypothesis might also help explain the increased longitudinal growth of bones in which the diaphysis had been the site of fractures or had been used as a donor site for a bone graft (Compere and Adams, 1937).

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Massell, T. B.: The Fluorescein Wheel Test for Collateral Circulation in the Preoperative Evaluation of Patients with Aneurysms and Arteriovenous Fistulas. *Surgery* 1947 3 616.

Operative cure of an arteriovenous fistula of a major artery frequently necessitates quadruple ligation of the component arteries and veins. In order to avoid gangrene, it is necessary to be sure that the collateral circulation is adequate prior to the operation. Clinical observation of evidence of a large fistula and accurate localization of the lesion in relation to the collateral arteries give some clue to the state of the collateral blood supply but a more definite test is necessary.

The Matas-Moskowitz flushing time gave variable results with different observers. The Matas compressor would slip as the position of the extremity was changed so that blood flowed through a supposedly occluded artery.

A new method for testing the collateral circulation which was based on the use of wheal fluorescence was devised. The aneurysm is occluded by a Matas compressor. A series of parallel scratches is made less than 8 cm. apart both on the involved and on the opposite extremity. Ten cubic centimeters of 10 per cent fluorescein are injected into an arm vein and the level of wheal fluorescence is examined by filtered ultraviolet light. If the collateral circulation is adequate, the lowest level of fluorescence should not be more than 8 cm. higher on the involved extremity than on the normal side.

Twenty-eight patients with aneurysms or arteriovenous fistulas were examined before operation by this technique and by the Matas-Moskowitz test. Wheal fluorescence seems to have the following advantages over the flushing time test for the collateral circulation.

1. Wheal fluorescence provides a clear and definite end point which is not subject to individual variation depending on the person who performs the test.

2. There is no arbitrary time limit. The criterion of normal value is provided in the opposite extremity in each observation.

3. Since the extremity does not have to be moved during the test, there is less danger of error from slipping of the compressor.

4. The fluorescein wheal test requires a briefer period of arterial compression than the flushing time technique and is therefore less painful to a hyper-sensitive patient.

Certain defects common to both tests were pointed out by the author. The improvement in the collateral circulation following sympathectomy was measured with both of the tests.

THOMAS B. MASSELL, M.D.

Rector, E. W.: Evaluation of the Basal Vascular Tone Test as an Indication for Sympathectomy in the Treatment of Surgical Lesions of the Major Arteries. *Surgery* 1947 630.

The development of the collateral circulation after ligation of a major artery may often be aided by sympathectomy performed previous to or at the same time as the arterial ligation. The benefits of sympathectomy are most marked in the patients in whom the vasomotor tone is increased.

Following the technique of Nalide and Sayen, measurements of the skin temperature were made with the aid of a galvanometer in a constant temperature room at 20°C and 40 per cent humidity. The digital skin temperature was measured at the start of the test and every 10 minutes thereafter. The values of the skin temperature readings obtained 30 minutes after the patient was admitted to the constant temperature room served as a final reading.

The clinical evidences of increased vasomotor tone were also observed, i.e., cyanosis, sweating, and constricted veins. The results of the test were compared with the clinical impression in 45 patients. There was agreement in 35 cases. In 10 of the 15 cases in which there was disagreement it was possible by analysis of the end results to compare the value of the two methods. Clinical judgment was found to be superior to evaluation by the basal vascular tone test in 8 of the cases while in only 3 cases the test for basal vascular tone proved to be superior to clinical appraisal of the patients.

The author points out that his patients were vigorous young individuals, all of whom had sustained local trauma to the blood vessels. The original work of Nalide and Sayen was based on an older group of individuals with arterial occlusions of more gradual onset.

In order to explain the discrepancy between the two reports it is suggested that abnormal vasoconstriction may be induced by local trauma and that this segmental arterial spasm may be quite independent of the general vasomotor tone.

BLOOD TRANSFUSION

Swedberg, Birger; Windström, Gösta; and Alin, Knut: The Importance of Aseptic Technique and the Fallaciousness of Chemical Bacteriostatics in Blood Banking and Plasma Preservation. *Acta med. scand* 1947 17 480.

The authors describe the work done elsewhere on bacteriostasis in blood preservation. In connection with the production of plasma for military use in Sweden during the period from 1943 to 1944 a very open method of blood drawing and plasma separation was used with the great possibility of consequent bacterial contamination. By the addi-

Cartwright G. R.: Dietary Factors Concerned in Erythropoiesis. *Blood* 1947 2 111 256

Knowledge concerning the production of the red cells is not nearly as complete as that concerning their destruction. Although hemin has been synthesized in vitro by Fischer and Zelle there is little evidence to indicate that such steps take place in vivo. It is the purpose of this review to describe those dietary factors now recognized as necessary for erythropoiesis and to discuss the present knowledge concerning them.

The known factors concerned in the formation of the red cell may be divided into three groups: vitamins, amino acids and minerals. Because of our lack of knowledge, it will be necessary to consider the formation of the erythrocyte and hemoglobin as one process erythropoiesis.

VITAMINS

Riboflavin, nicotinic acid, pyridoxine, and the various folic acids are important for red cell formation in at least one species each.

A. The role of riboflavin in blood regeneration in dogs on a purified ration has been studied by Spector, Maas, Michaud, Elvehjem, and Hart, and they concluded that it plays a role in determining the size of new red cells. Wintrobe, Bushke, Follis, and Humphreys found the development of anemia in a riboflavin-deficient pig which survived a long time. A moderate impairment in the rate of red cell and hemoglobin regeneration in the rat as a result of riboflavin deficiency has been demonstrated. Unmistakable anemia has been reported in monkeys. Upon administration of riboflavin there is a definite increase in the hemoglobin, red cell and white cell counts in the blood. There is no true evidence that riboflavin deficiency in man results in anemia. Myelin degeneration of the peripheral nerves and posterior columns of the spinal cord occurs in riboflavin-deficient dogs. It was thought that this vitamin might play a role in the etiology of subacute combined degeneration of the cord. That riboflavin is not the extrinsic factor has been conclusively demonstrated. Klein and Kohn have shown that the synthesis of flavinadenine dinucleotide from riboflavin takes place in human blood cells both in vitro and in vivo. It seems possible that this enzyme may be related to erythropoiesis or hemoglobin synthesis. It is known that flavinadenine nucleotide and Spector *et al* have suggested that this vitamin may be concerned in the metabolism and arrangement of the amino acids of globin.

B. Nicotinic acid. Handler and Featherston demonstrated that the parenteral administration of physiological saline solution to dogs with acute black tongue resulted in alleviation of the existing hemolysis and was associated with the appearance of severe anemia. This responded immediately to the administration of nicotinic acid or nicotina

tion of sulfathiazole 100 mgm./100 c.c. and rapid cooling of the blood and with plasma preparation within 5 days it was believed that bacterial growth in the blood might be prevented. The plasma was stored when ready at between -15 and -25°C and sterilized by filtration immediately before drying. The clinical results with this plasma were generally good. However plasma which was undried showed almost constantly bacterial and fungoid growth after from 12 to 18 months. When contaminating organisms are found they are generally resistant to sulfathiazole even in concentrations of 500 mgm./100 c.c. The authors re-emphasize the importance of aseptic methods from the moment of blood collection to the dispensation of the finished plasma. No bacteriostatic agent can take the place of aseptic technique.

EDWARD H. CAMP, M.D.

Muirhead, E. E., Small, A. B., and McBride, R. B.: Peritoneal Irrigation for Uremia following Incompatible Blood Transfusion. Report of a Case. *Arch. Surg.* 1947 54 374.

The authors report a case of uremia following incompatible blood transfusion which was successfully treated by peritoneal irrigation. The method followed by Frank, Seligman and Fine in acute renal failure following sulfathiazole therapy was utilized.

Through a cleral or a white female patient aged 36 received an incompatible blood transfusion. For 16 days following and prior to the institution of peritoneal irrigation, the patient's condition gradually deteriorated, the azotemia became progressively worse, and the signs and symptoms of grave uremia followed. The prognosis was such that the patient was not expected to survive.

Peritoneal irrigation with a sump aspiration drain in the right lower quadrant and a No. 18 rubber French catheter in the left upper quadrant was then employed for 6 days. The solutions used were serial of the crystalloid types containing heparin and penicillin. Substantial amounts of urea were obtained by this extrarenal route, and the azotemia was promptly and greatly relieved. Subsequently the kidneys cleared large quantities of urea from the body, but polyuria was necessary as the urea clearance remained depressed.

Overhydration constituted one of the main complications as the kidneys were unable to rid the body of water. This condition was apparently aggravated by the use of Tyrode's solution and an isotonic solution of three chlorides in the peritoneum. Recovery was associated with the loss of water and salt from the body while dextrose in distilled water was used for peritoneal irrigation.

A low grade peritonitis was controlled by parenteral and intraperitoneal streptomycin. Circulatory failure associated with oligemia was successfully treated by the intravenous administration of blood plasma and electrolytes. The patient left the hospital 38 days after the reaction and her urea clearance at the time of discharge was 33 per cent of normal.

EDWARD F. LEWIS, M.D.

mide. Histological examination of the tissues of 1 dog was made and revealed hemosiderosis of the spleen. Erythropoiesis appeared to have stopped at the erythroblast level. These authors postulated that since immature nucleated erythrocytes require they probably use pyridine nucleotides in this respiration. As the supply of nicotinic acid diminishes, anemia develops because of the lack of coenzyme in the earliest stages of cell development. Nutritional pancytopenia in rats has been reported as being prevented by nicotinic acid. The association of anemia with pellagra has long been known. This has been reported as varying in from 44 to 84 per cent of the cases. There is no evidence that the anemia associated with pellagra is due to nicotinic acid deficiency. Proof that such an anemia exists in man is lacking. Gastric achlorhydria occurs in approximately 80 per cent of the patients with pellagra.

C. Pyridoxine. The development of severe anemia has been adequately demonstrated to result from pyridoxine deficiency in dogs and swine. A mild anemia develops in pyridoxine-deficient chicks and in this species, the anemia is accompanied by a decreased clotting time, hyperprothrombinemia, and small spleens. Morphologically, the anemia in dogs and swine is microcytic and slightly hypochromic. It is severe in both species and develops in other species within 2 months. The bone marrow in pyridoxine-deficient swine is hyperplastic. Following therapy with crystalline pyridoxine the marrow becomes normoblastic. Hemosiderosis of the spleen, liver and bone marrow has been reported in swine. Following therapy the hemosiderosis of the liver and bone marrow disappears and that in the splenic pulp diminishes. Ataxia and convulsions have been reported in both dogs and swine and pathologically the nervous system shows interesting changes. Degeneration takes place in the peripheral nerves, spinal ganglia, posterior roots, and the dorsal funiculi of the spinal cord. It would seem that pyridoxine like the antipernicious anemia substance and copper is essential to the integrity of both the nervous and hematopoietic systems. There is no evidence for the presence of a hemolytic element in pyridoxine-deficiency anemia. Elevated plasma iron levels in dogs were reported by Fouts *et al.* The serum iron increase has been studied in detail in swine and begins at about the fourth week of deficiency. Combined iron and pyridoxine deficiency results in an abnormally low serum iron level and in this combined deficiency hemosiderosis of the tissues is prevented. It would seem that the ferremia of pyridoxine deficiency is caused by continued retention of iron at a time when its utilization for hemoglobin synthesis is at a minimum. The possibility exists that the absorption of iron is increased in pyridoxine deficiency. Ninety-five per cent of the increased iron in the serum is in a nondialyzable, ferric state. Copper, unlike iron, is not mobilized in the blood of the severely anemic animal. There is no evidence to date that pyridoxine is directly concerned with the synthesis or metabolism of the porphyrins.

It has been shown that a relationship exists between pyridoxine and tryptophan metabolism. Since a deficiency of either pyridoxine or tryptophan gives rise to anemia, the question arises as to whether the two substances combine to form a third which is essential to blood formation. This is not the case. In swine, combined pyridoxine and iron deficiency results in a greater anemia than does either deficiency alone.

Pyridoxine has never been conclusively demonstrated to be essential to human nutrition. Pyridoxine-deficiency anemia resembles pernicious anemia in several respects. In both conditions there is an increase in serum iron, hemosiderosis of the tissues, hyperplastic bone marrow and neurological lesions. That they are not the same is evidenced by a macrocytosis in one and a microcytosis in the other.

D. Lactobacillus casei factors. The various new factors described as having growth activity for the *Lactobacillus casei* and related organisms are many. Recently considerable clinical interest has developed in this group of substances because of the demonstration of the effectiveness of the synthetic *Lactobacillus casei* factor in various macrocytic anemias in relapse.

The value of folic acid (pteroylglutamic acid) in various types of macrocytic anemia in relapse has now been adequately demonstrated and repeatedly confirmed. Spies *et al.* observed a reticulocyte response and an increase in the red cell count in patients with macrocytic anemia in relapse. The drug was given orally to 4 patients in a dose of from 100 to 150 mgm. daily and parenterally to 5 patients in a dose of from 10 to 50 mgm. Moore, Bierbaum, Welch and Wright noted clinical and hematologic remissions in 2 patients with Addisonian pernicious anemia following the daily oral administration for 10 days of 30 mgm. and 100 mgm. of the synthetic material respectively. The response was excellent. Observations on the effectiveness of synthetic folic acid in the treatment of Addisonian pernicious anemia have now been confirmed many times. A daily dose of from 5 to 10 mgm., either orally or parenterally will often produce a maximal response. Synthetic folic acid has been found to be effective in alleviating the hematologic as well as many of the other manifestations of sprue. The administration of from 15 to 200 mgm. daily is followed by a reticulocytosis and rise in the leucocytes, platelets, red count, hemoglobin, and volume of packed red cells to normal. The glossitis disappears in 3 or 4 days, after which there is rapid regeneration of the papillae. There is an improved sense of well being, an improvement in appetite, and a decided gain in body weight. Synthetic folic acid has been found to be effective in the treatment of nontropical nutritional macrocytic anemia of infancy with megaloblastic bone marrow, macrocytic anemia of pregnancy, macrocytic anemia associated with alcoholic cirrhosis of the liver and macrocytic anemia associated with carcinoma of the stomach. No response to folic acid has been observed in cases of aplastic anemia, leukemia, or iron deficiency anemia. Folic acid has not been of value in

correcting the leucopenia of influenza, or the pan hematopenia of myelophthisic and idiopathic states. It does not prevent the development of agranulocytosis in a patient receiving thiouracil.

Spies and coworkers have administered large doses (from 4 to 12 gm.) of thymine to 10 patients with Addisonian pernicious anemia. The clinical and hematological improvement was found to be similar to that which follows the administration of folic acid to such patients. The authors speculate that perhaps folic acid acts as an enzyme or coenzyme in the synthesis of thymine or a thymine-like compound. This naturally leads to questions as to the identity of the extrinsic factor, the intrinsic factor, and the anti-pernicious anemia substance in liver as postulated by Castle. It can be stated that the folic acid is probably not the extrinsic factor alone since it acts orally in the absence of normal human gastric juice and is effective parenterally.

E. Extrinsic factors. It has now been 17 years since Castle first presented evidence concerning a dietary factor which when incubated with a factor in normal human gastric juice formed a substance effective in the treatment of pernicious anemia. Beef muscle, yeast, wheat germ, milk, purified casein, liver eggs and rice polishings have been shown to contain significant amounts of the factor. The active factor can be removed from beef muscles by repeated extractions with dilute acetic acid or by extraction with from 70 to 80 per cent alcohol. It is water soluble, thermostable, resistant to alkalization, readily soluble in from 70 to 80 per cent alcohol but is rapidly destroyed in 95 per cent alcohol. The active substance is ultrafiltrable and cannot be extracted from an 80 per cent alcoholic solution with ether. Following saturation of an alcoholic extract of beef muscle with ammonium sulfate the activity is found in the precipitate. The existence of an anemia due to a deficiency of Castle's extrinsic factor has been clearly demonstrated by Moore, Vilter, Minnich and Spies. These workers have described the occurrence of macrocytic anemia in 56 patients who had existed for years on diets inadequate in animal protein and in the vitamin B complex. Most of the subjects had at one time shown clinical evidence of pellagra, riboflavinosis or beriberi. The most striking clinical manifestations were weakness, pallor, glossitis, skin changes, and intermittent or persistent diarrhea. The anemia was cytologically indistinguishable from true Addisonian pernicious anemia, and the bone marrow was the same in the two conditions. Following the administration of an 80 per cent alcoholic extract of beef muscle a reticulocytosis developed and after prolonged administration the erythrocytes increased in number. All of the patients responded promptly to the parenteral injection of highly purified liver extracts. Studies on the pathogenesis of the anemia indicated that it was probably caused by a dietary deficiency of extrinsic factor associated in many but not all instances with poor absorption from the intestinal tract. The anemia, leucopenia and thrombocytopenia all respond rapidly to pteroyl

glutamic (folic) acid therapy. The occurrence of macrocytic anemia of nutritional origin in India has been reported.

F. Ascorbic acid. It has been conclusively shown that the scorbutic state in guinea pigs as well as in human beings is frequently accompanied by anemia. The nature of this is in dispute.

This has been demonstrated in guinea pigs and the addition of ascorbic acid to a scorbutogenic diet prevents the development of the anemia.

The frequent occurrence of anemia in human scurvy has been reported by many authors. The red cells have been reported as being macrocytic, normocytic, and microcytic or hypochromic. The exact causal relationship still remains to be established and the literature is confusing.

AMINO ACIDS

Because of the difficulty in preparing a diet deficient in a single amino acid only a few experiments of such a nature have been conducted. These included deficiencies of tryptophan, lysine, and phenylalanine.

Rats fed a diet abnormally low in protein but adequate in all other respects develop anemia which responds to protein therapy.

The minimal molecular weight of hemoglobin has been shown to be about 16,700 and studies of the osmotic pressure and of the sedimentation constant have shown that the true molecular weight of anhydrous hemoglobin is close to 66,600 which indicates that hemoglobin is composed of four globin units.

No single amino acid appears to be more important than the others in hemoglobin synthesis.

For some time it has been known that tryptophan accelerates recovery and causes a prompt reduction in the reticulocytosis seen in anemia caused by phenylhydrazine. By acid hydrolysis of casein it has been possible to prepare a protein which is almost totally deficient in tryptophan. By this means the anemias as a consequence of deficiency have been studied. The results have not been conclusive.

Since a lack of either tryptophan or of pyridoxine leads to the development of anemia and since there is a disturbance of tryptophan metabolism in pyridoxine deficiency the question arises whether pyridoxine anemia may be due to a lack of properly metabolized tryptophan. If this were true the two anemias should be similar but they are quite different. It is known that deamination of casein destroys the entire content of lysine, about half of the histidine and a portion of the tyrosine. Hogan and Ritcho reported that rats maintained on deaminized casein develop anemia and splenomegaly. When casein was added to the deaminized casein ration the anemia failed to develop.

MINERALS

Iron. That iron is a constituent of the hemoglobin molecule and that a deficiency of iron gives rise to an anemia are both well established.

1. **Availability.** Dietary iron is of two types, organic and inorganic. The organic iron is present

principally in the form of iron porphyrin compounds. The ability of inorganic iron salts to cure iron deficiency anemia has been well demonstrated in many different species. On the other hand it has been shown that organically bound iron is very poorly utilized when given orally. Organic iron if it is to become available, must be converted to an ionizable form. In the case of hematin it has been shown that less than 25 per cent has been utilized and this utilization appears to be dependent upon the amount of decomposition by intestinal bacteria. It would seem that the body's need for iron can be entirely satisfied by inorganic iron compounds.

2. Absorption. Iron is absorbed chiefly in the duodenum but the stomach and the whole of the small intestine may take part under certain circumstances. It is doubtful if this occurs in the colon. It is absorbed by the tips of the villi of parts of the duodenum and from there is passed into the portal circulation and is carried to the liver.

a. Type of iron. It is generally believed that iron is absorbed in the soluble, ionizable, ultrafiltrable, ferrous form. The absorption of ferric compounds is generally less than that of ferrous compounds and is dependent on the capacity of the intestinal contents to reduce them. Organically bound iron is very poorly absorbed. Using the radioactive iron technique, it has been demonstrated in two different laboratories that human subjects absorb ferrous iron more efficiently than ferric iron. There is a species difference, however, and this may account for the disagreement between clinical and animal investigations.

b. Amount of iron. The height of the serum iron increase is directly proportional to the amount given up to that point at which intestinal irritation is great enough to interfere materially with intestinal motility.

c. Gastric acidity. The free gastric hydrochloric acid performs two functions: (1) reducing, ionizing, and dissolving the iron and (2) delaying the formation of insoluble and undissociated iron compounds which may occur above pH 5. For these reasons any factors which cause increased alkalinity diminish iron absorption.

d. Conditions in the duodenum. The pH of the duodenal contents likewise affects the ionization and solubility of the iron compounds. The presence of certain reducing substances in the diet aids the absorption of iron. Liver extract is such a substance. The reducing properties of ascorbic acid are well known.

e. Calcium/potassium ratio and vitamin D. There is ample evidence that excess calcium in the diet inhibits iron assimilation and causes a mild anemia. Furthermore all investigators are agreed that iron utilization is affected by the calcium/potassium ratio in the diet but there is disagreement as to whether a high or low ratio is favorable.

f. Selective absorption. There is considerable disagreement concerning this factor.

g. Other factors. There is suggestive evidence that pyridoxine may regulate iron absorption.

3. Transportation. There is now ample experimental evidence that there is a fraction of iron in the plasma which is in a nonhemoglobinous form. The significant fact concerning plasma iron is that it has been demonstrated to function as transport iron. It is interesting that transportation and utilization are very rapid processes. The normal range for plasma iron in human beings has been shown to be about from 0.050 to 0.180 mgm. per cent. The plasma iron level is affected by the rate of absorption of iron, the balance between that going to and from the tissues, and the equilibrium between the amount used for hemoglobin formation and that coming from hemoglobin catabolism. In general, in iron deficiency states it is uniformly low. Under conditions of decreased red cell formation, it tends to be high. When the bone marrow is unusually active the plasma iron is low. In hemolytic states the plasma iron level is dependent upon the equilibrium between the iron released by hemolysis of red cells and the rate of uptake by the bone marrow.

Barkan has described a third form of blood iron, constituting 5 to 10 per cent of the total blood iron, which he termed the "leicht abspaltbare Bluteseisen" fraction. This was so named because it was easily freed from its lightly bound state in the erythrocytes and plasma by acidification with weak acids.

4. Storage of iron. Although the literature on this phase of iron metabolism is very extensive the storage of iron is poorly understood. The immobile fraction of body iron is made up of parenchyma iron and the iron in myoglobin. This constitutes about 25 per cent of the total body iron. Parenchyma iron is probably held tightly by the cells in such forms as cytochrome, catalase, peroxidase, and other cellular enzymes and is essential to the life of these cells. Myoglobin has been shown to be very similar to hemoglobin in respect to the absorption, iron content, and elimination by way of bile pigments, but may be differentiated by means of a specific precipitation reaction.

In the dog, Whipple and his coworkers concluded that the liver, spleen, and bone marrow are the principal sites of storage iron. Fifty to 70 per cent of the iron injected intravenously can be shown to be stored in the liver and spleen. The liver contains the main bulk of the iron stored and is considered the most important organ in the conservation and utilization of iron in the body. The turnover in the liver is exceedingly rapid if there is a demand for the element for blood formation. However the spleen contains the highest reserve stores of iron per 100 gm. of fresh tissue. The iron content of the rib bone marrow runs parallel with that of the spleen.

Little is known concerning the chemical nature of the stored iron. Approximately 60 per cent of the iron in thoroughly perfused liver is in protein combination, in so far as it is removable from solution by precipitation with trichloroacetic acid. It has been shown that 43 to 60 per cent of the iron in perfused adult rat liver reacts directly with pyridine in the presence of a reducing agent and must, therefore, be

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

127

OTORHINOLARYNGOLOGY

The program in otorhinolaryngology will consist of two evening symposia, three morning panel discussions from 10:45 to 12:15, and an evening session on Wednesday in which a combined program with the ophthalmologists will be held. The fact that the morning panel discussions are planned this year to follow those on ophthalmology instead of being held simultaneously, will enable surgeons who combine these specialties in their practice to attend both sessions.

The subjects for the evening symposia will be Tuesday—Bronchiectasis Thursday—"Surgical Management of Carcinoma of the Larynx."

The subjects for the Wednesday evening combined session are listed in the preceding section on ophthalmology.

Tentative subjects for the panel discussions are as follows: Repair of Bilateral Adductor Paralysis of the Vocal Cords, Anesthesia for Ear, Nose and Throat Surgery and Rhinoplasty.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday and Friday mornings. The Forum affords a large surgical audience the opportunity to become acquainted with the work of many productive clinical and experimental investigators through the medium of the concise presentation at the same time it gives a number of young, well-trained surgeons their first opportunity of a hearing before a national surgical organization. It is the professed purpose of the Surgical Forum as expressed by Dr. Owen H. Wangenstein, Chairman of the Forum Committee, to attempt to bring before its assembly each year the best that is new in surgery, announcement of new found knowledge of special interest to surgeons and wider dissemination of new significant information in the interphases between surgery and allied medical specialties suggests the objectives which the sponsors have in mind in the formulation of programs for presentation.

Selection of papers for the New York Clinical Congress is now being made by the committee, which is guided by originality of thought and interest suggested in the abstract submitted by the author. Each speaker is allowed 10 minutes for his presentation.

A total of 93 talks were given at the Surgical Forums in Cleveland.

SPECIAL SYMPOSIA

A symposium on fractures and other traumas will be held on Tuesday afternoon, a symposium

on cancer on Wednesday afternoon and a symposium on graduate training in surgery on Thursday afternoon.

SPECIALTY PANEL DISCUSSIONS

Panel discussions on the surgical specialties will be held on Friday afternoon hours and programs to be announced later. The panels will be held concurrently in the following fields: orthopedic surgery, neurosurgery, plastic surgery, obstetrics and gynecology, urology and thoracic surgery.

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty-sixth Hospital Standardization Conference. Dr. Irvin Abell of Louisville, President of the College, will preside. The hospital conferences will continue on Monday afternoon with sessions following on Tuesday, Wednesday and Thursday mornings, afternoons and evenings.

Hospital administrators, members of governing boards, heads of the various hospital departments and their personnel, nursing groups, and many other persons directly or indirectly concerned about hospital progress will be interested in the discussion of current hospital problems. National organizations representing various groups of hospital personnel will co-operate and participate in the meetings which will include formal sessions, panel discussions, round table conferences, and open forums.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. These are a much appreciated feature of the Clinical Congress.

Both sound and silent standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be located in the Basildon Room, Jade Room, and Astor Gallery all on the third floor of the hotel. Leading manufacturers of surgical instruments, lead apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the new features learned from our experience in the war.

in some form of chemical combination other than that of the iron in hematin. About 60 per cent of this non-hematin fraction appears in the trichloroacetic acid precipitate. The total iron in a trichloroacetic acid filtrate reacts directly with potassium cyanate in acid solution after oxidation with hydrogen peroxide and this fraction accounts for about 40 per cent of the nonhematin iron. About 50 per cent of the total iron in the trichloroacetic acid filtrate is precipitated along the organic substances by normal lead acetate. The digestion of fetal calves' livers, adult rats' livers and muscle tissue, and beef spleen by pepsin at about pHs produces a five fold increase in the iron content of the trichloroacetic acid filtrate.

There is an appalling lack of knowledge concerning hemosiderin. It is recognized that it is the iron-containing portion of hemoglobin which rests in the cells of most tissues but especially is it found in the spleen, liver and kidney following the destruction of erythrocytes. Hemosiderin probably represents some stage or side reaction in the disintegration of hemoglobin into bile pigment but the exact nature of the reactions involved is not understood. There is little doubt that it functions as storage iron for the granules are abundant following repeated injections of ferric chloride and disappear when the demands of the body for iron are great.

5. Anemia of iron deficiency. The anemia of iron deficiency and its response to iron are well recognized. A hypochromic, microcytic anemia is characteristic of iron deficiency and has been described in different species. In the advanced stages marked anisocytosis and polikilocytosis of the red cells are present. The Price-Jones curves in severe cases show a marked shift to the left with a broad base. In the absence of iron, hemoglobin cannot be synthesized and there is a maturation arrest at the normoblastic stage. The bone marrow is hyperplastic and shows a predominance of the more mature nucleated red blood cells principally the polychromatic normoblasts. There is no evidence that there is an increased rate of destruction of red cells. Porphyrin metabolism has been inadequately studied in iron deficiency. The normal erythrocyte protoporphyrin ranged between 20 and 45 gamma per 100 c.c. of erythrocytes. It has been demonstrated that the serum iron level is low in iron deficiency anemias of varied etiology.

6. Excretion. It has long been claimed that iron is excreted by three routes: urine, bile, and the large intestine. It is now agreed that only a minimal amount of iron is excreted in the urine. It has been shown that the urinary excretion of iron is rather constant in the same individual and that it is not related to iron intake. There is evidence that significant amounts of iron are eliminated in the bile under certain circumstances. Under conditions of increased blood destruction the elimination of biliary iron may increase tenfold and parallels the increased output of bile pigment, but even then only 3 per cent of the released iron is eliminated in the bile. It would seem that the body controls the iron stores by controlling the absorption rather than its elimination and that

once iron gains entrance into the body it remains there.

B. Copper. It has now been demonstrated many times in several different species that copper is needed in addition to iron in order either to prevent or to cure the anemia.

In the treatment of nutritional anemia in infants it has often been demonstrated that when iron therapy is combined with copper therapy the rate of hemoglobin formation is more rapid than when the anemia is treated with iron alone. The livers of anemic infants have revealed a lower copper content than the livers of nonanemic controls. There is little evidence to indicate that iron alone is as effective as combined iron and copper therapy in infants.

The value of copper in the treatment of hypochromic microcytic anemia in adults is controversial. In general, the consensus of most hematologists is that the adult patients with hypochromic microcytic anemia in the absence of infections, malignancy and continued hemorrhage will respond satisfactorily and rapidly to iron medication. In nutritional anemia in infants the rate of hemoglobin formation is accelerated when copper is given in addition to iron. In adults supplemental copper therapy may be of value in a few cases. Most cases will respond if adequate doses of iron are given.

The absorption and excretion of copper in man has been little studied. The daily requirement of copper for adults is from 1 to 2.5 mgm. It has been estimated that the adult body contains between 100 and 150 mgm of copper. During embryonic life copper becomes concentrated in the liver and reaches a maximum concentration at term. There is then a sharp decline after the second month. The copper content of the liver has been noted to be increased in Mediterranean anemia, hemochromatosis, cirrhosis of the liver, acute yellow atrophy of the liver, tuberculosis and carcinoma. It is now agreed that the range for whole blood copper in normal adult males is approximately from 90 to 150 micrograms per cent, while that for normal adult females is approximately from 100 to 160 micrograms per cent. Copper is distributed approximately equally between the cells and the serum.

Many investigators have reported the presence of increased blood copper during pregnancy. Sachs and his group have made studies on whole blood copper as well as iron at various ages. In all the conditions studied there has been an inverse relationship between the copper and iron content. As the iron falls the copper content tends to rise. Hypercupremia is the usual response to hypoferrremia.

Elevated serum copper values have been reported in pregnancy and in infections accompanied by anemia. In both of these conditions there is a low serum iron. The serum copper content is subject to diurnal variations but is not affected by menstruation.

7. The function of copper. The precise manner in which copper is related to the formation of red cells is not understood. It is not a constituent of the hemoglobin molecule. Since the administration of

copper to anemic rats is followed by a rise in the erythrocyte count without a rise in hemoglobin. It has been postulated that copper is essential for stroma formation of the cell or for the release of erythrocytes from the bone marrow rather than for hemoglobino-genesis. When iron is fed to iron and copper deficient animals the total iron content of the liver and spleen increases in proportion to the amount of iron fed. Thus in the absence of copper iron is absorbed and stored normally. If copper is then fed to these animals in the place of iron hemoglobin formation takes place and the iron content of the liver and tissue is reduced to a level of that found in severely anemic animals. From this it has been concluded and accepted that copper is essential for the mobilization of iron from the tissues and for its conversion into hemoglobin or, stated in another manner, copper acts as a "catalyst" for the formation of inorganic iron into hemoglobin.

There are numerous other recognized functions of copper. It has been shown that copper is essential for the activity of at least 3 enzymes. The oxidation of crystalline glutathione is accelerated in the presence of small amounts of copper. The catalytic effect of copper on the oxidation of cysteine as well as ascorbic acid has been reported. Glycolysis is known to be activated by copper and accelerated in anemia

C. Cobalt. The role of cobalt in erythropoiesis is unique. A deficiency results in anemia. The administration of small amounts to normal animals produces erythrocytosis, whereas the administration of large amounts depresses erythropoiesis. The enzootic occurrence of cobalt deficiency has been reported from several regions of the world. Anemia is present and is often severe. The anemia is either normocytic or microcytic and usually hypochromic. Blood smears reveal anisocytosis and poikilocytosis. There is a hypoplasia of erythropoietic tissue in the bone marrow, hemosiderosis of the tissues and a reduction in reticulocytes in the blood. An experimental anemia due to cobalt deficiency has not been produced in either rats or dogs. There is no substantial or convincing evidence that cobalt is needed by human beings for normal erythropoiesis. The administration of small amounts of cobalt to normal rats, dogs, guinea pigs, frogs, mice, rabbits, chickens, pigs, and ducks produces a marked polycythemia which is accompanied by a reticulocytosis, hyperplasia of the bone marrow and an increased erythropoietic activity in the spleen and liver. Larger doses of cobalt inhibit erythropoiesis. The metabolism of cobalt is unlike that of iron. The excretion of cobalt once it is absorbed is exceedingly rapid and is principally through the kidneys. LE ROY J. KLEINERMAN, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Livingston, K. E.: Extremity Refrigeration without Tourniquet Ligation in Cases of Acute Arterial Deficit. *Ann. Surg.*, 1947 125 431

The author discusses the experimental studies carried out by Allen in 1938 and 1939, when he demonstrated that intact limbs can survive complete ischemia for significant periods if absolutely cooled. In 1941 these observations were applied clinically to amputation under tourniquet ligation and refrigeration. This method now has real value in preparing for and reducing the risk of amputation in the presence of advancing gangrene and toxic absorption or in cases of massive trauma to the limb. Limbs to be amputated by this method are ligated by tourniquet and cooled to levels of 2 to 8 degrees centigrade above freezing. Changes which are probably irreversible occur in the tissues. These are the combined result of cooling and of complete ischemia produced by the tourniquet. On the basis of present clinical experience, tourniquet ligation and refrigeration are appropriate only as preparation and cannot be safely employed when survival of the limb is anticipated. There is evidence clinically and experimentally that the more severe changes may be attributable to tourniquet ischemia rather than to cooling. The author believes it is therefore possible that refrigeration with out tourniquet might be successfully employed in some cases of acute vascular deficit in which survival of the limb is anticipated.

The author cites a few clinical reports of refrigeration without tourniquet followed by amputation, but no pathological studies were made of the amputated extremities so no conclusions could be drawn. He cites one other case in which pathological studies were made and this revealed that the distal circulation of leg and foot was remarkably preserved. However the conclusions in this case were pessimistic.

The author then cites his own experience. Following an acute and severe vascular accident secondary to traumatic aneurysm of the popliteal artery cooling of the distal extremity was carried out for 28 days prior to amputation. During the interval of observation changes which were assumed by all observers to have been irreversible regressed and the appearance of the foot strikingly improved. Following amputation there was gross and microscopic evidence that revascularization was taking place in the cooled tissues and that the nutrition of the deep muscle tissues and weight-bearing skin and subcutaneous tissue of the foot had been well maintained. These studies did not indicate that the smaller circulation in the cooled areas had been extensively shut down by vasoconstriction due to

cold. The author was impressed by the wealth of small patent vessels in all tissues and also by the active recanalization processes in the thrombosed segments of major arteries.

It is believed that further clinical experience would be valuable in confirming or modifying these views and suggested that in the future more adequate cooling be used and that it be combined with alcohol block or lumbar sympathectomy because vasospasm may be a significant factor.

G ALLEN LAVA, M.D.

Shaffer, J. O.: A Method of Rapid Transfusion into the Femoral Vessels in Patients without Adequate Peripheral Superficial Veins. *Surgery* 1947 21 659

When rapid transfusion is required in a patient whose superficial veins are thrombosed or difficult to enter the author advocates that the femoral vessels be used. If the femoral artery has a good pulsation, the common femoral vein is usually patent and should be used. A 20 gauge needle $2\frac{1}{2}$ inches long with a short bevel is inserted just medial to the arterial pulsation and just below the inguinal ligament, perpendicular to the skin. As the needle is advanced to a depth of 2 to $3\frac{1}{2}$ cm. dark venous blood will appear in the syringe. Aspiration of 5 to 10 c.c. of blood reinjection and respiration insures that the needle point is well placed in the lumen of the vein. When a patient is in such profound shock that the pulsation of the femoral artery cannot be felt the femoral vein is usually collapsed and unsuitable for venipuncture. The artery should then be used, the puncture being made just distal to the inguinal ligament and at the midpoint between the anterior superior iliac spine and the pubic tubercle.

When the needle has been well placed it should be secured in position with three small Kelly forceps. These grasp the needle as close to the skin as possible each forceps being placed 120 away from the other two. The three forceps should then be taped firmly to the skin of the thigh and abdomen. In most instances it is also advisable to restrain the patient's leg.

Blood, plasma or fluids may be allowed to drip or may be forced into the vessel under pressure. When the infusion has been discontinued momentary pressure over the site of puncture is sufficient to prevent hematoma formation.

B F LOOMIS, M.D.

Golnard, P., Ferrand, J. and Tardieu, P.: Post-operative Complications in Alcoholics (Sur ces tains accidents post-opératoires graves des éthyliques). *Lyon chir.*, 1947 43 56

A group of characteristic complications occur in chronic alcoholic patients following operation. They usually begin about the first postoperative day and consist of fever, progressive agitation, delirium

tremens, and oliguria. In many instances death ensues. Eight cases are cited to illustrate the typical history of this syndrome in chronic alcoholics who underwent a gastrectomy for ulcer.

The authors have instituted a definite regimen to control and prevent this syndrome. Treatment consists of large doses of strychnine which are apparently well tolerated by these individuals. The dosage varies from 15 to 36 mgm. daily according to the clinical response and the severity of the disease, it is given every 2 hours and usually continued for 3 days sometimes 5 or 6. In addition betulin, liver extract and intravenous fluids are given. Sedation, in general to control the agitation has proved unsatisfactory although of the common hypnotics used, chloral hydrate seemed best.

This particular group of postoperative complication can be avoided by proper preoperative management. One week of complete preoperative rest with complete alcoholic abstinence, and a high carbohydrate consumption are recommended. Strychnine is given in daily doses of from 6 to 18 mgm. for 5 to 7 days accompanied by betulin, hepatic extracts and small doses of insulin.

Certain precautions should be taken during operation. Because of the unstable circulatory system in chronic alcoholics, the use of general anesthesia and administration of intravenous fluids are hazardous. Postoperative treatment is based on establishing a proper fluid balance and giving large doses of strychnine. Vitamin K should be used if any tendency toward bleeding is present. The authors suggest hepatic insufficiency as the basis for this syndrome.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Vaughan, J., Thomson, M., and Dyson, M.: The Blood Picture and Plasma Protein Level following Injury. *J. Path. Bact. Lond.* 1946, 58: 749.

The authors describe their observations on the blood picture, serum bilirubin, plasma proteins, and urinary urobilin in a series of 14 patients following various types of injury. These were divided into three groups: (1) injuries other than those due to enemy action; (2) industrial injuries in which superficial burns were associated with fractures, and (3) injuries due to enemy action.

The findings irrespective of the character of the injuries, revealed the following:

During the first week there was a fall in the hemoglobin and red cells, and either a fall in the plasma proteins or an initial low level. In regard to the differential proteins, albumin decreased but this was accompanied by a rise in globulin and fibrinogen. A rise in the reticulocytes preceded a rise in hemoglobin and was associated with a rise in the red cells and plasma proteins. The serum bilirubin was higher in the first few days, although within normal limits, and the urobilinogen in the urine was noticeable in several cases.

The authors then discuss these findings and their causation, concluding with the suggestion that the anemia occurring during the first 10 days after injury is not due to blood loss or hemolysis but to a disturbance of hemoglobin synthesis dependent upon disordered liver function. In view of their findings in these patients they stress the importance of a high protein intake in all surgical cases.

G. ALAN LIVA, M.D.

Corcoran, A. C. and Page, Irvine H.: Crush Syndrome. *J. Am. M. Ass.* 1947, 134: 436.

Traumatic shock is thought of as an acute state from which no threatening conditions persist. Crush syndrome was rediscovered, named and studied on a wider scale during the London blitz.

Typically the syndrome is initiated by crushing of a limb or occlusion of its arterial supply for several hours. Release from debris or restoration of the blood flow is followed by swelling with wheal formation at the sites of compression. The limb becomes hard paralyzed and anesthetic. Loss of plasma into the area of injury causes hemoconcentration. Shock may supervene and be relieved by transfusion. Urine passed during the first 24 hours is colored red or brown with myoglobin, contains albumin, and shows many brown and black granular pigment casts. The urinary output and specific gravity thereafter diminish. The patient passes into rest, less delirium with thirst and vomiting. Arterial pressure and the concentration of serum potassium are increased. Azotemia rises until about the sixth day when death suddenly occurs in about two-thirds of the cases. The volume of urine of those who are to recover increases about this time and their renal function is slowly restored in the succeeding months.

The exact mechanism of hemoglobinuric nephrosis is not established. There is compelling evidence which associates it with urinary acidity.

Others believe that renal injury in the crush syndrome is a consequence of prolonged arterial hypotension with renal ischemia and anoxia.

The mechanism of crush syndrome can be visualized as follows:

Vasoconstrictive renal ischemia occurs with the onset of shock or even of injury. The urine is acid and small in volume. The muscle cells are fragmented so that when the circulation is restored through the crushed areas myoglobin diffuses into the blood whence it is filtered into the renal tubules. Thus the conditions of pigmentary precipitation (aciduria oliguria) are encountered while the kidney is further damaged by the lack of blood flow. It has been demonstrated that hemoglobin precipitation in the renal tubules is facilitated by prior injury whether from ischemia or injection of a nephrotoxic (tartrate). However it is not clear from these experiments whether the factor responsible was cellular injury as such, or oliguria resulting therefrom. In either case the conditions of precipitation are present in crush syndrome.

The major renal lesion in crush syndrome is epithelial. Renal epithelium is sensitive to a variety of toxins.

Treatment is directed toward the underlying mechanisms.

The primary problem in renal damage is the renal ischemia. This is due to vasoconstriction.

Thus the basic preventive measures in crush syndrome are: (1) pressure bandaging of the injured limb, (2) rapid treatment of shock with restoration of the blood pressure, (3) provision of adequate fluid, (4) provision of a diuretic, and (5) the administration of an alkali.

HARRY W. FOX, M.D.

Brush, B. E., Lam, C. R., and Ponka, J. L.: *Wound Healing Studies on Several Substances Recommended for the Treatment of Burns*. *Surgery* 1947 21: 662.

Although marked advances have recently been made in the therapy of burns there is still a considerable vogue for the use of ointments and other topical applications. Few of the agents employed have been subjected to critical examination of their effect on wound healing.

The authors have investigated a group of substances commonly employed in the treatment of burns, as well as some experimental ointments submitted by the Subcommittee on Burns and Surgical Infections of the Committee on Medical Research. The substances tested were tannic acid solution, tannic acid in tragacanth jelly, commercial tannic acid jelly (Amertan), petrolatum gauze, two kinds of carbowax ointment, a mineral oil and aluminum monostearate preparation, proflavine dihydrochloride, bitydine ointment, and hydrosulfosol solution. Each substance was tested on 12 guinea pigs. The animal's abdomen was aseptically prepared and two circular cutaneous defects were made, one on each side of the midline. The wound on the left was used as the test wound and the other as a control. The side of the test wound and the other as a control. The test material was then applied to the wounds, and the wounds were outlined on sterile cellophane, and the test material was then applied to the wounds. Sterile dressings were applied firmly to the wounds, and were changed every 2 days until the wounds had both healed. At each change of dressings new cellophane records of the size of the wound were made.

None of the substances studied showed an appreciable accelerating effect on wound healing. All the tannic acid compounds showed definite inhibition of wound healing. Petrolatum gauze had no effect. Both types of carbowax ointment delayed wound healing slightly. Proflavine dihydrochloride and bitydine were mildly inhibitory. The stearate monostearate was also slightly inhibitory. The grease-treated wounds healed in the same time as the controls.

B. F. LOCKSLEY, M.D.

Colebrook, L., Duncan, J. M., and Butterfield, W. J. H.: *Added Infections in Burns*. *Lancet* London, 1947 1: 331.

This article is a report of further study of infection acquired apart from dressing of the wound

The investigation overlaps that reported by Bourdillon and Colebrook (1946). It deals with the 12 months from August 1, 1945 to August 1, 1946 during which period was recorded the time when the wound was dressed, the type of cover (perfect or imperfect) on the wound and exposure of the wound (if any) since the last dressing.

Daily records were kept showing the order in which patients were dressed, the clinical condition and the bacteriological flora of the burned areas at the time of dressing.

Organisms used as indicators for added infection are the hemolytic streptococcus, the *Pseudomonas pyocyanea* and the *Bacillus proteus* because of ease of identification and because these 3 are more often associated with delayed healing and unsuccessful grafting operations.

In most cases the burn was covered with tulle gras, then dry sterile gauze, then absorbent cotton and last, crepe bandages. A light shell of plaster of Paris is often applied in the cases of children.

The term "added infection" is used to denote the growth of 1 of the 3 indicator organisms from burned areas which had been free from such infection on admission, such infection having been obtained during the hospital stay.

Included in the authors' records in this article were records of whether the burned areas were in completely covered and whether they were liable to infection from without.

In the period covered by this article no dressings of fresh burns were carried out in the open wards. All first dressings were done in rooms which were not supplied with dust free air. All except 107 of the subsequent 1,419 dressings were done in a dust free atmosphere.

The data summary showed that of the 220 patients with burns free from all indicator organisms on admission 29 (13.2%) acquired one or more during their hospital stay. In 28 of these the infection probably was acquired in the ward during the interval of dressing.

It is shown that the incidence of added infection was closely related to success or failure in keeping the burned areas adequately covered with dressings. It also seemed obvious to the authors that the added infection had arisen by transfer of infective material from sources outside of the patient.

Clouds of pathogens are liberated during bed changes and when dressings are applied. The clothing of doctors, nurses, and visitors (especially those with throat infection), flies, drinking utensils, bed pans, thermometers, toys, and materials of occupational therapy are other sources of infection.

The following procedures seem to the authors of chief importance in the prevention of added infection in the wards:

1. Maintenance of perfect cover. The recommended dressing is to cover the burned area with sterile gauze, then wool (3/4 to 1 inch thick) and finally crepe bandage. This should be supported by adhesive and in an active child by a light plaster-of

Paris cast over the crepe bandage. Daily careful examinations of the bandage during ward rounds are essential.

2. Restraint of bacterial growth on the burns, and elimination of reservoirs of infection. For routine dressing the authors have used for the past 3 years a cream containing penicillin and sulfathiazole in a bland base (Clark *et al.* 1943) with very satisfactory results. After the first application of this cream, the dressings are left undisturbed for from 7 to 12 days, and subsequent dressings for from 5 to 7 days. If hemolytic streptococci were found on culture a course of 4 or 5 applications of penicillin cream at 3 day intervals was instituted with excellent results in eliminating reservoirs of this organism.

3. Rapid repair of epithelial skin covering. It is difficult to keep large granulating surfaces free from all added infections for many weeks. The longer the burned area is kept uncovered with epithelium the more fibrous tissue is formed beneath it; this often leads to serious dysfunction. For this reason grafting as early as possible is recommended and should be repeated without delay. Repeated regrafting with stored skin or with small grafts should be a routine dressing procedure.

4. Antidust measures and the elimination of flies. Oiling of blankets after laundering (Harwood *et al.* 1944) and of floors (Andrews *et al.* 1940) are 2 simple methods advocated. Frequent spraying of D.D.T. in white spirit plus screening will take care of flies.

5. Segregation of infected cases in cubicles. Ideal burn units would be single units for half of the bed accommodations and for the rest bed rooms to accommodate 2 to 4 patients.

6. Routine purification of the air of wards. Whatever methods are used, frequent cleaning of the air of wards with burn patients is a desirable goal.

The incidence of added infection in burns which were found to be imperfectly covered when redressed was 10 times as high as that of the burns which had a perfect cover during the interval between dressings.

The problem of controlling added infections of burns with the *Staphylococcus aureus* remains untouched but the authors state that the elimination of these infections is likely to present great difficulties because of the great prevalence of this organism.

DAVID H. REED M.D.

Ritter A., and Pletscher A.: The Treatment of Wounds with Sulfonamides. A Clinical and Experimental Histological Report. (Wundbehandlung mit Sulfonamiden. Klinischer und experimenteller histologischer Beitrag.) *J. internat. chir. Brux.* 94b, 6-61.

The authors studied the effects of the various sulfonamides on clean and infected wounds in guinea pigs. The sulfonamides used were chloranil, ilicosin, haptocil and irgamid which are the European equivalent of sulfanilamide, sulfathiazole, sulfapyridine and sulfadiazine. They studied histologically

the tissue in which the sulfa drugs had been introduced 1, 12 and 24 hours later and from 2 to 14 days later. They found that the degenerative changes in the subcutaneous tissue and the muscle were somewhat more marked following the use of sulfonamides than in the controls, but also found that the connective tissue regeneration was greater at the same time. They found that edema and cellular infiltrations were less marked in infected cases following the chemotherapeutic treatment, but that the wounds did not heal as readily as the infected ones even though the connective tissue regeneration was more pronounced. They state that the slight delay in wound healing was usually caused by too much sulfonamide powder or crystal in the wound and around the tract of the wound.

They conclude from their surgical experience and their experimental work that the local application of sulfonamide in infected or traumatic wounds is definitely beneficial and increases tissue reaction and connective tissue regeneration. They warn against using too much drug, and emphasize that the use of sulfonamide drugs should never take the place of primary surgical treatment of the wound.

GEORGE PYRETT M.D.

Domagk, Gerhard: Present Day Status of Chemotherapy of Bacterial Infections by Sulfonamides (Der derzeitige Stand der Chemotherapie bakterieller Infektionen mit den Sulfonamiden) *Deut. med. Wochschr.* 947 72 6, 71.

The bacteriostatic effect of sulfonamides is dependent on different factors. One of these is the chemical constitution. Those compounds in which the sulfonamide group (SO_2NH_2) is in a p-position to the amino-group are more effective than others. The bacteriostatic effect is not diminished when the hydrogen atoms in the NH group as well as in the SO_2NH_2 group are substituted. Of special interest are experiments with certain anaerobic organisms, like the *Bacillus welchii*. In vitro these bacilli are very little influenced by the most used sulfonamides like prontosil, sulfapyridine, and sulfathiazole, but they show a specific sensitivity to the German product marfanil $\text{H}_2\text{N}-\text{H}_2\text{C}-\text{SO}_2\text{NH}$ and its derivatives in which the amino group is not linked directly to the phenol ring but to a methyl group in p-position to the sulfonamide group.

The simplest method to test the influence of a compound on different species of bacteria is to add the drug to ordinary laboratory media, preferably agar or blood agar and to inoculate the bacillus on this medium. The degree of the effect depends on 3 factors: the species and strain of the organism, the compound used and the culture medium. The bacteriostatic effect varies considerably with the same compound in different media. In vitro, bacteriostasis occurs in concentrations between 1 to 10,000 and 1 to 80,000.

It would however be wrong to draw too far reaching conclusions from laboratory experiments.

Many compounds, e.g. the original prontosil, which are quite successful clinically and in animal experiments have only a poor bacteriostatic effect in vitro. The reasons for this difference are manifold. In the first place, some drugs are changed chemically after their introduction into the organism into substances which are more effective than the original product. Furthermore, the phagocytic action of the sulfa compounds and the phagocytic action of the leucocytes, histiocytes, and other elements of the reticuloendothelial system is necessary to develop an optimal action on the bacilli. Phagocytosis of the organisms which have been paralyzed by the sulfonyl compounds is essential for a full therapeutic effect. It has been shown that bacteria were phagocytized in the presence of sulfonamides if they had not been attacked by phagocytes previous to the sulfonamide treatment. This change is due to the bacteriostatic effect of the drug not to any stimulation of the leucocytes.

In animal experiments with phlegmonous cellulitis caused by highly virulent streptococci the author showed that in untreated animals no walling off of the focus occurred and the phlegmon spread without any resistance. Very soon after onset of the sulfa treatment, however, more and more leucocytes could be observed to be invading the focus phagocytizing the streptococci and walling off the entire area.

Although the author agrees that the action of sulfa compounds is mainly bacteriostatic, he believes that some bactericidal effect takes place too especially under conditions unfavorable to the growth of the organisms, such as poor media and increase of temperature to 39 or 40° C. This observation is further supported by the fact that patients with high fever show a quicker and more intensive response to sulfa treatment than those with low grade fever or normal temperatures.

During the war infections with the different bacilli of gas gangrene were rampant in Germany not only in war wounds but also complicating appendicitis, cholangitis, perforating peptic ulcer and other abdominal pathology. In these cases, topical and systemic application of the sulfonamides gave excellent results. Whereas before the sulfonamide period the mortality in perforating appendicitis was as high as 14 per cent, it dropped to 1 per cent under sulfa treatment.

As to wounds, especially battle wounds which were exposed to infection the author suggests routine treatment (topical and systemic) with a mixture of 2 sulfa compounds, one effective against aerobic, the other against anaerobic bacilli.

The indications, the technique of application and the dosage are discussed in detail, as well as the different compounds which have been used in Germany during the war (Since the author uses only proprietary names in his article it could not be ascertained in most cases what compounds were used (marfanil, marbada, debenal). The German eludron is identical with sulfathiazole.

The author stresses the importance of topical application in surgical cases
WERNER M. SOLMITS, M.D.

Shaffer J O : Intra Arterial Penicillin in the Surgical Treatment of Infections of the Extremities. *Surgery* 1947 21 693

The author describes his method of injecting penicillin intra-arterially in the treatment of infections of the extremities. The intra arterial route of administration of drugs was apparently first utilized by Heddaus, in 1914, when he injected antitetanic serum into the carotid. Subsequently numerous other workers have employed a great variety of therapeutic agents, seeking to obtain a high local concentration within certain tissues by injection of the drug directly into the artery supplying those tissues. In infections of the extremities often large areas are involved, and the penicillin penetration becomes a problem because of impaired blood supply or because the infection lies within bony or fascial pockets. When penicillin is injected intra-arterially the dilution remains minimal, and the blood pressure forces the concentrated drug into the tissues.

The author makes use of a blood pressure cuff applied to the extremity distal to the point of injection and inflated to a subdiastolic pressure. This prevents the return of venous blood and yet permits the continued arterial pressure to distribute the drug. An ingenious use of radioactive phosphorus, traced to its ultimate destination by Geiger counters, demonstrated that this method of injection gave a higher concentration of injected material for a longer period than did intravenous injection or intra-arterial injection without a cuff or with a cuff inflated to supra diastolic pressure. The actual injection is done with a 20 c.c. syringe attached to a 20 gauge needle 2 1/2 inches long. The point of maximum pulsation of the femoral artery just below the inguinal ligament (or the brachial at the elbow or the distal portion of the axillary for the upper extremity) is palpated, and the artery is steadied with the index and middle fingers of the left hand. The needle is then inserted perpendicular to the skin between the steady fingers. A pulsating bright red stream showing in the syringe indicates that the needle point is within the arterial lumen. When the injection has been completed the site is subjected to temporary digital pressure to prevent hematoma formation. The dosage used by the author has been 500,000 Oxford units of penicillin in 10 c.c. of normal saline. One or two daily doses should be given until optimal results have been obtained.

Types of infections successfully treated by the author in his series of 40 patients included diabetes, arteriosclerosis, osteomyelitis, suppurative joints, infected ulcerations, infected operative incisions, and various types of gangrene. He observed no hematoma in any of his cases as a result of the arterial puncture.

The only contraindications to the procedure are phlebotromboses and infections of the skin overlying the artery.

ing the proposed site of injection. When procaine is given along with the penicillin, local anesthesia is obtained and simple surgical procedures may be performed
B. F. LOEWENBERG, M.D.

Bowle, J. H., and Borcar, M. D.: Continuous Injection of Penicillin: the Secunderabad Apparatus. *Lancet* London 1947 1: 477

The authors—a penicillin research team (India Command) at Secunderabad—cite their experiences in treating war wounds chiefly unhealed compound fractures of the femur. Because of the difficulties experienced in these cases when penicillin was administered by three-hourly injections or by the ordinary Army saline-giving sets, they were prompted to develop a method for the continuous administration in small volume. They concluded that penicillin should be injected continuously in as small a volume as possible and that rubber tubing be avoided. Since the amount of sodium penicillin commonly administered in 24 hours is readily soluble in 2 milliliters of water it was believed that a vial should be attached to the patient and some means evolved to depress the piston slowly over a period of hours.

The authors give a detailed explanation of this apparatus which is fitted with needles which are suitable for subcutaneous, intramuscular or intravenous use.

The authors describe the advantages of the apparatus as follows: (1) an absolutely constant injection ensuring a maximum constant blood penicillin level at a minimal expenditure of the drug; (2) possibility of blockage in the needle during injection is eliminated; (3) supervision is unnecessary except when set up on the patient and when recharged at 24 hour intervals; (4) the small volume (2 ml.) in which the penicillin is injected reduces proportionately (a) pain and local edema and (b) deterioration of the penicillin at room temperature; (5) the patient is not confined to bed but to the length of his cable and may leave the ward by separating the cable at an appropriate point; (6) booster doses can be given at any time; (7) according to the number of cable adapters fitted to the distribution box on the motor, any number of patients in a ward can be treated simultaneously; (8) there is no contact with rubber tubing; and (9) it may be used in research on the action of other drugs.

The authors observed that blood-penicillin levels became constant throughout the day and night after a "building up" period directly proportional to the dose and inversely proportional to the patient's weight. They found that for every 0.02 unit of penicillin required in the serum, a dose of 25,000 units a day per 140 pound of body weight must be given. From this datum the dose required to obtain the required blood-penicillin level in any patient can be calculated by proportion. The dose of penicillin required for an particular patient may be estimated if the resistance of the invading pathogen and the patient's body weight are known.

C. ALBIN LIVA, M.D.

ANESTHESIA

11 Ghos, E. S. R.: Refrigeration Anesthesia. *Br J Anaesth* 1947 1: 761

Twenty-five cases of amputation under refrigeration anesthesia are reported with details of the individual cases and the technique employed. This method of anesthesia was reserved for "bad risk" cases. Progressive gangrene of the foot complicated by severe pain or infection was most frequently the cause for amputation. The underlying constitutional pathology was "atherosclerosis" or "diabetes mellitus."

The technique of refrigeration used is simple. No costly apparatus is necessary. A wooden box lined with galvanized iron sheeting is filled with chipped ice and this is kept at room temperature overnight to allow the sharp edges to be melted away. The tourniquet is not an essential requirement at any stage of the procedure and may be dispensed with entirely but its employment is advisable. The period of time for which the limb is refrigerated depends on the relation of the local lesion to the general condition of the patient. If the former is the cause of depression of the latter then by cooling the lesion to 5°C at which level metabolism is minimal, it becomes physiologically disconnected from the body. If the patient has severe pain and toxemia the affected area of the limb is refrigerated for several days without a tourniquet several hours before operation the refrigerated area is extended to just above tourniquet level. The minimum time for which a limb may be safely refrigerated before operation varies from 2 to 3 hours. Amputation is carried out as in cases with the usual form of anesthesia. There is no primary shock despite the fact that the patient remains fully conscious throughout surgery.

Complications were occasionally secondary shock, bronchopneumonia, and most frequently infection.

Experimental and practical evidence is convincing that refrigeration anesthesia is a sure means of excluding a constitutional depressant, and a useful measure in certain "bad risk" cases.

JOHN E. KRAVITZ, M.D.

Saklad, Meyer, Dwyer, Clement, S., Kronenberg, Sanford, Neves, Edmund, and Sorkin, Morris: Intraspinal Segmental Anesthesia: A Preliminary Report. *Anesthesiology* 1947 8: 270

A technique of obtaining a segmental distribution of spinal anesthesia is presented. A limited number of spinal nerve roots are bathed by an anesthetic solution within the subarachnoid space. This is accomplished by injecting a solution of pontocaine hydrochloride in a dilution of 1 to 1000 through a fine catheter which has been passed cephalad within the subarachnoid space for a distance of from 15 to 25 cm. The total dose of pontocaine is a small fraction of that ordinarily required for spinal anesthesia.

This preliminary report includes the authors' first 24 cases of intraspinal segmental anesthesia for abdominal surgery. In 20 cases the anesthesia was sat-

isfactory and in a cases there was technical failure because of faulty placement of the catheter.

The dilute solution of pontocaine hydrochloride in spinal fluid may be considered to be nearly isotonic, isobaric, and isohydronic. Local toxic effects and neurologic sequelae are, therefore, less likely to result. The accurate deposition of such a weak solution of anesthetic agent within the subarachnoid space reduces the hazard of respiratory paralysis.

Persistence of motor power in the lower extremities may result in a more efficient return flow of blood to the heart and may have a beneficial effect on the systemic circulation during anesthesia. Maintenance of muscle tone in the legs may result in a decreased incidence of phlebotrombosis and postoperative urinary disturbances may be less common.

Dripps, Robert D.; and Sergeant, Warren F.: Use of a New Curarizing Agent, Dihydro-Beta Erythroidine for the Production of Muscular Relaxation during Anesthesia and Surgery *Anesthesiology* 1947 8 241

This preliminary report concerns the intravenous administration of a relatively new curarizing agent dihydro-beta-erythroidine to 215 patients receiving general anesthesia. No attempt was made to select cases. Cyclopropane ethyl ether sodium pentothal and nitrous oxide were the anesthetic agents employed.

Dihydro-beta-erythroidine decreased or abolished the conduction of impulses from nerve to skeletal muscle in a curariform fashion. Muscles were af-

fected in the same sequence as with curare. Satisfactory surgical relaxation was recorded in 96 per cent of the cases. The drug seems indistinguishable in this regard from curare. The decrease in respiratory minute volume was accomplished almost entirely by a diminution in depth per breath. Respiratory rate remained relatively unchanged or increased. A paralytic effect was exerted on the striated laryngeal muscles.

Hypotension occurred in 86 per cent of the patients. The amount of blood pressure decrease was related in part at least to the amount of drug administered. The impression was gained that the degree of hypotension produced was also related to the level of anesthesia. The fall in blood pressure was a transient phenomenon as a rule lasting from 5 to 10 minutes. It is thought the reaction is related primarily to depression of the medullary vasoconstrictor center or to paralysis of the sympathetic ganglia with diminution of the arteriolar tone.

The circulatory depressant action described suggests the possibility of direct depression of the medullary vasomotor center. There is also other evidence in man and animals which indicates that curare and the erythrine alkaloids depress the central nervous system.

The initial dose which the authors recommend is between 50 and 75 mgm. if ethyl ether anesthesia is employed and between 75 and 100 mgm. if the anesthetic agent is cyclopropane. The major complication of intravenous administration of dihydro-beta erythroidine was the hypotension.

MARY FRANCES POZ, M.D.

ing the proposed site of injection. When procaine is given along with the penicillin, local anesthesia is obtained and simple surgical procedures may be performed.

B. F. LOCKHART, M.D.

Bowle J. H., and Borcar M. D.: Continuous Injection of Penicillin: the Secunderabad Apparatus. *Lancet* Lond., 1947 1: 477

The authors—a penicillin research team (India Command) at Secunderabad—cite their experiences in treating war wounds, chiefly unhealed compound fractures of the femur. Because of the difficulties experienced in these cases when penicillin was administered by three hourly injections or by the ordinary Army saline-giving sets, they were prompted to develop a method for the continuous administration in small volume. They concluded that penicillin should be injected continuously in as small a volume as possible and that rubber tubing be avoided. Since the amount of sodium penicillin commonly administered in 24 hours is readily soluble in 2 milliliters of water it was believed that a syringe should be attached to the patient and some means evolved to depress the platen slowly over a period of hours.

The authors give a detailed explanation of this apparatus which is fitted with needles which are suitable for subcutaneous, intramuscular or intravenous use.

The authors describe the advantages of the apparatus as follows: (1) an absolutely constant injection ensuring a maximum constant blood penicillin level at a minimal expenditure of the drug; (2) possibility of blockage in the needle during injection is eliminated; (3) supervision is unnecessary except when set up on the patient and when recharged at 24 hour intervals; (4) the small volume (2 ml.) in which the penicillin is injected reduces proportionately (a) pain and local edema, and (b) deterioration of the penicillin at room temperature; (5) the patient is not confined to bed but the length of his cable, and may leave the ward by separating the cable at an appropriate point; (6) booster doses can be given at any time; (7) according to the number of cable adapters fitted to the distribution box on the motor, any number of patients in a ward can be treated simultaneously; (8) there is no contact with rubber tubing; and (9) it may be used in research on the action of other drugs.

The authors observed that blood penicillin levels became constant throughout the day and night after a "building up" period directly proportional to the dose and inversely proportional to the patient's weight. They found that for every 0.02 unit of penicillin required, the serum a dose of 25,000 units a day per 140 pound of body weight must be given. From this datum the dose required to obtain the required blood-penicillin level in any patient can be calculated by proportion. The dose of penicillin required for any particular patient may be estimated if the resistance of the invading pathogen and the patient's body weight are known.

C. ALLEN LIVA, M.D.

ANESTHESIA

Hughes, E. S. R.: Refrigeration Anesthesia. *Brit M J* 1947 1: 761

Twenty five cases of amputation under refrigeration anesthesia are reported with details of the individual cases and the technique employed. This method of anesthesia was reserved for "bad risk" cases. Progressive gangrene of the foot complicated by severe pain or infection was most frequently the cause for amputation. The underlying constitutional pathology was "atherosclerosis" or "diabetes mellitus."

The technique of refrigeration used is simple. No costly apparatus is necessary. A wooden box lined with galvanized iron sheeting is filled with chipped ice and this is kept at room temperature overnight to allow the sharp edges to be melted away. The tourniquet is not an essential requirement at any stage of the procedure and may be dispensed with entirely, but its employment is advisable. The period of time for which the limb is refrigerated depends on the relation of the local lesion to the general condition of the patient. If the former is the cause of depression of the latter then by cooling the lesion to 5°C. at which level metabolism is minimal, it becomes physiologically disconnected from the body. If the patient has severe pain and toxemia the affected area of the limb is refrigerated for several days without a tourniquet several hours before operation the refrigerated area is extended to just above tourniquet level. The minimum time for which a limb may be safely refrigerated before operation varies from 2 to 3 hours. Amputation is carried out as in cases with the usual form of anesthesia. There is no primary shock despite the fact that the patient remains fully conscious throughout surgery.

Complications were occasionally secondary shock, bronchopneumonia and most frequently infection.

Experimental and practical evidence is convincing that refrigeration anesthesia is a sure means of excluding a constitutional depressant, and a useful measure in certain "bad risk" cases.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However, in order to insure against overcrowding, attendance at the Congress will be limited to the number that can be accommodated at the clinics and meetings. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

Because of greatly increased costs and expenses to which the College will be subjected this year in connection with its New York Clinical Congress, the Board of Regents has found it necessary to require a registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non-Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1947.

To each surgeon who registers in advance a formal receipt will be issued. This is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card is not transferable and must be presented in order to obtain clinic tickets and admission to scientific sessions.

The registration desk will be open from 4:30 to 9:00 p.m. on Sunday, September 7, in order to permit surgeons to obtain tickets for the Monday clinics. A new plan is to be adopted in New York of distributing clinic tickets on the day prior to the clinics from 9:00 a.m. to 5 p.m. Any remaining tickets will be available at 7:00 a.m. the same day on which the clinics are held.

HOTEL RESERVATIONS

Although the prospect is that the hotel situation in New York will be more favorable than it would have been last year nevertheless there is still a critical shortage of hotel rooms and early reservations are most desirable. In making these, communications should be addressed to the New York Convention Bureau, through which all reservations for the Clinical Congress are to clear. No correspondence should be sent directly to the hotels. A letter has been sent to Fellows in which the procedure is outlined. With this letter was enclosed a form to be used in making reservations. Choices of hotels may be designated. The following hotels are recommended by the Committee

Dripps, Robert D.; and Sargent, Warren F.: Use of a New Curarizing Agent, Dihydro-Beta Erythroidine, for the Production of Muscular Relaxation during Anesthesia and Surgery. *Anesthesiology* 1947 8: 241.

This preliminary report concerns the intravenous administration of a relatively new curarizing agent, dihydro-beta-erythroidine, to 215 patients receiving general anesthesia. No attempt was made to select cases. Cyclopropane ethyl ether sodium pentothal and nitrous oxide were the anesthetic agents employed.

Dihydro-beta-erythroidine decreased or abolished the conduction of impulses from nerve to skeletal muscle in a curanform fashion. Muscles were af-

fected in the same sequence as with curare. Satisfactory surgical relaxation was recorded in 96 per cent of the cases. The drug seems indistinguishable in this regard from curare. The decrease in respiratory minute volume was accomplished almost entirely by a diminution in depth per breath. Respiratory rate remained relatively unchanged or increased. A paralytic effect was exerted on the striated laryngeal muscles.

Hypotension occurred in 86 per cent of the patients. The amount of blood pressure decrease was related in part at least to the amount of drug administered. The impression was gained that the degree of hypotension produced was also related to the level of anesthesia. The fall in blood pressure was a transient phenomenon as a rule lasting from 5 to 10 minutes. It is thought the reaction is related primarily to depression of the medullary vasoconstrictor center or to paralysis of the sympathetic ganglia with diminution of the arteriolar tone.

The circulatory depressant action described suggests the possibility of direct depression of the medullary vasomotor center. There is also other evidence in man and animals which indicates that curare and the erythrine alkaloids depress the central nervous system.

The initial dose which the authors recommend is between 50 and 75 mgm. if ethyl ether anesthesia is employed and between 75 and 100 mgm. if the anesthetic agent is cyclopropane. The major complication of intravenous administration of dihydro-beta erythroidine was the hypotension.

MARY FRANCES POE, M.D.

with or without mediastinal shift to the opposite side. In the presence of associated pneumothorax there is a horizontal fluid level.

Loculated or encapsulated hemothorax is characterized by fibrous pleural bands enclosing an accumulation of blood, with or without air at various levels in the pleural cavity. On the roentgenogram loculated hemothorax may be represented as various sized and irregularly distributed fluid levels.

Clotted hemothorax occurs in from 4 to 6 per cent of cases with hemothorax. Roentgenologically clotted hemothorax may assume a variety of appearances. There may be mottling, multiple fluid levels, densely thickened pleurae, or signs of traction. These may appear alone or in combinations.

Empyema from pleural sepsis in battle casualties is given variously from 11.9 per cent in penetrating, and 11.3 per cent in nonpenetrating wounds to 23 and 33 per cent respectively.

Atelectasis is commonly found in association with thoracic wounds subsequent to compression phenomena, injury to the bronchial tree, and a mucus plug occurring as a postoperative complication. Its appearance on the roentgenogram varies from streak to platelike densities to massive opacities. In the latter instance there is retraction of the mediastinum to the same side, narrowing of the rib interspaces, and elevation of the diaphragm.

Bronchopleural fistulas occur infrequently in thoracic wounds and generally follow in the wake of empyema, sinus tract or surgery.

Blast or concussion injuries to the lungs following waves of compressed air brought to bear upon the thorax occur in about 2 or 3 per cent of the cases. The roentgenological features of blast injury are treelike densities involving the pulmonary fields usually most prominent at the bases.

Transdiaphragmatic injuries occur in 10 per cent of battle injuries of the chest and have a 25 to 40 per cent mortality rate. Hepatopleural fistulas may be present or become manifest after admission. In penetrating wounds of the diaphragm immediate or delayed herniation of the abdominal organs may follow. On the roentgenogram, diaphragmatic hernia must be differentiated chiefly from empyema cavity, loculated pneumothorax, interlobar fibrosis, lung abscess, eventration of the diaphragm, pulmonary cyst, and giant emphysematous blebs. Subphrenic abscesses constitute an additional complication.

Penetrating missiles occasionally leave roentgenologic evidence of their passage through lung tissue in the form of tracks. FRANK L. HENNEY M.D.

Henny G. C., Boone, B. R., and Chamberlain, W. E.: The Electrokytograph for Recording Heart Motion Improved Type. *Am J Roentg* 947 37 409.

The authors report and describe the electrokytograph for recording the electrokytograph for recording motion with use of the roentgenoscopes. The apparatus employs a roentgen device which when properly placed,

gives a cardiac silhouette translates the motion of this silhouette border into a varying electrical current. The current is recorded with the aid of a standard electrocardiographic machine.

They also describe the construction of a carotid pulse recorder which is used to record the pulse in conjunction with the heart border motion.

FRANK L. HENNEY M.D.

Dexter Lewis: Venous Catheterization of the Heart. Results, Interpretations, and Value. *Radiology* 947 48 45.

The author presents the findings in representative types of congenital heart disease. In the presence of an auricular septal defect, blood usually flows from the left auricle to the right auricle. The venous catheter is helpful in the recognition of this defect by two methods. The catheter may be introduced through the defect or arterial blood may be found in the right auricle.

An uncomplicated defect in the interventricular septum results in the shunting of arterial blood from the left ventricle to the right ventricle. Its recognition by venous catheterization depends on the finding of a significantly higher content of blood in the right ventricle than in the right auricle.

The tetralogy of Fallot consists of pulmonary stenosis, an interventricular septal defect, over-riding or dextroposition of the aorta, and right ventricular hypertrophy. Because of the pulmonary stenosis, venous blood enters the pulmonary artery with difficulty and some is shunted through the septal defect and into the aorta. The patients are, therefore, cyanotic, and suffer mainly from a deficient blood flow through the lungs. The venous catheter may follow one of two courses. It may pass through the stenosed pulmonary valve into the pulmonary artery or it may pass through the interventricular septal defect and go directly into the over-riding aorta.

Patent ductus arteriosus is a vascular anastomosis between the aorta and pulmonary artery which during fetal life serves to bypass the lungs. Its persistence after birth is deleterious, because of the case with which bacterial vegetations become implanted and also because of the circulatory strain thrown on the left ventricle. Since the flow of blood after birth is from the aorta, where the pressure is high to the pulmonary artery, where it is low there is no cyanosis and the lesion is detectable on venous catheterization by the finding of arterial blood in the pulmonary artery or in other words, blood with a higher oxygen content in the pulmonary artery than in the right ventricle.

Venous catheterization promises to be an important aid in the preoperative diagnosis of congenital cardiac disease. FRANK L. HENNEY M.D.

Stenstrom, E. W.: Roentgen
Diagnosis. *Radiology*, 947

ity of Hodgki
The cases
led into

two series, one series comprising 185 cases, proved histologically, the other, 53 cases in which Hodgkin's disease was found clinically the biopsy specimens having been examined at other institutions. All patients were treated from 1926 through 1942 and were followed through December 1945.

Many different titles have been given to diseases in the lymphoblastoma group. The most common title, and one which avoids confusion, is Hodgkin's disease. The etiology of Hodgkin's disease is still undetermined. Some authors have attributed it to a tubercle bacillus others believe it may be due to a diphtheroid bacillus, brucella, a filtrable virus, or to a neoplasm.

The symptomatology and physical findings of Hodgkin's disease are variable. Sometimes the only complaint may be enlarged lymph nodes, generally in the cervical or axillary region with systemic symptoms such as fever, weakness, anorexia, and loss of weight. A concomitant upper respiratory infection may be present, with a dry hacking cough which is generally indicative of mediastinal involvement. Dyspnea, cyanosis, or dysphagia are frequently seen when mediastinal involvement is present. Backache may be due to enlarged retroperitoneal lymph nodes. Pruritus is due either to a lymphangitic infiltration in the skin or to enlarged lymph nodes.

The pathology of Hodgkin's disease is divided by most authorities into three groups: (1) the paraneoplasia which is benign; (2) the granuloma which presents a serious prognosis; and (3) Hodgkin's sarcoma, which is highly malignant.

Hodgkin's disease is to be differentiated from leukemia, lymphosarcoma, and tuberculous adenitis. Its incidence in all races is equal and it occurs more frequently in males (70%) than in females. In 27 per cent of cases the disease develops during the third decade of life. In 61 per cent of cases the site of onset is in the peripheral lymph nodes and in 10 per cent of cases in the axillary lymph nodes. In 83 per cent of the authors' cases the cervical lymph nodes were involved.

Each case should be considered individually and no set routine of radiation therapy should be attempted. An average dose of 1,000 tissue roentgens should be given. In some instances as much as 2,000 roentgens may be delivered to the areas in which the condition is localized in cases in which lesions have been present for quite some time, a much heavier dose is necessary. The authors believe it unwise to treat an area prophylactically since it is impossible to determine the site of later tumefaction. Irradiation of the entire body has been carried out, but, in the opinion of the authors, total body irradiation in itself is not sufficient to check the progress of the condition, and it is their belief that it should be given

in conjunction with localized therapy. Fifty to 75 roentgens in air should be administered in cases of enlarged mediastinal lymph nodes (not the usual 250 or 300 roentgens) to avoid edema of the bronchi with compression and respiratory embarrassment.

An analysis of the authors' cases reveals that in general, the survival time of children was shorter than that of adults, the average survival being under 20 months. In the first series of 185 cases there was a 5 year survival rate of 21 per cent, and a 10 year survival rate of 8 per cent. The average duration of life was 33.1 months. MAURICE D. SACHS, M.D.

Warkany J. and Schraffenberger E. Congenital Malformations Induced in Rats by Roentgen Rays. *Am J Roentg* 1947 56 455

Roentgen rays have been used experimentally in rats to produce malformation, either by irradiating the sex gland of mature animals, or the pregnant female. In the first type, the germ plasma is injured and subsequent generations inbred are malformed. In the second type, the modifications are induced in the embryo which is often deformed at birth. The authors are concerned with the second type and primarily with skeletal malformation.

Pregnant rats of the Sprague-Hawley strain were irradiated on the tenth, eleventh, twelfth, thirteenth, fourteenth, fifteenth, and sixteenth day of gestation with a single dose of from 100 to 1,200 roentgens.

Malformations were induced in rats on the tenth to sixteenth day of gestation. Higher doses produced deformities of the brain, eye, and the upper and lower jaw. The relationship of dose to deformity was in direct ratio. For example, on the fourteenth day of gestation the rats were given a single dose of 100 to 250 roentgens, with the result that the litter appeared normal except for minor deformities of the fingers and toes. A dosage of 800 to 950 roentgens produced severe external malformations with 22 out of 24 cleft palates.

Variations were observed in the same litter. This was attributed to different stages of development.

Skull defects were seen only in those cases in which the rats were irradiated on the tenth, twelfth, thirteenth and, in a few instances, fourteenth day of gestation. Angulation of the ribs was seen in those rats which were irradiated on the fifteenth and sixteenth day of gestation. Cleft palate was particularly noted on the fifteenth day, the vertebral column was not affected.

Of the 622 young rats obtained from 144 mothers, 485 had skeletal deformities, primarily confined to the skull, cleft palate, short mandible, and angulation of the ribs, arms, and legs.

MAURICE D. SACHS, M.D.

1. Cysts secondary to fetal structural defects
 - a. Those resulting from failure of involution of normal fetal tracts, e.g. thyroglossal and bronchial cysts, Rathke's pouch cyst.
 - b. Aberrant tissues, e.g. accessory thyroid gland.
 - c. Cystic disease e.g. polycystic kidney and pulmonary, hepatic, or pancreatic cyst.
2. "True" tumors of embryonal or differentiated structure
 - a. Teratomas, teratoid tumors, and dermoids
 - b. Tumors of the following sites
 - (1) Nervous system—cranial, spinal cord, peripheral nerves, sympathetic system
 - (2) Eye and orbit
 - (3) Bones—benign and malignant
 - (4) Lymphatic and blood forming organs—leukemia, lymphosarcoma, and Hodgkin disease
 - (5) Genitourinary tract
 - (6) Somatic structures, including the skin, fat, connective tissue, muscle, vessels, nerves, and synovia.

Other tumors such as those of the breast, gastrointestinal tract, and endocrine glands also occur but because of their rarity during childhood are not discussed.

The author suggests a complete examination in accordance with the following schedule: from birth to 1 year—monthly; from 1 year to 6 years—quarterly; from 6 years to 12 years—semiannually; and from 12 years to maturity—annually (to include chest x-ray and blood study). D. W. H. L. M. D.

Jönsson, G. A New Method of Treating Capillary Hemangiomas. *Acta chir. scand.*, 947: 93-97.

Hemangiomas are benign tumors made up almost exclusively of vascular tissue which may be classified into two main groups: the capillary or telangiectatic type and the cavernous type. The latter consists of large irregularly shaped spaces generally communicating with each other and when most typical these tumors resemble normal erectile tissue.

Capillary hemangiomas are made up of a dense network of capillaries of a nearly uniform caliber with a sparse amount of interstitial tissue, and these tumors vary from pin head size to large patches sometimes involving an entire extremity or even one-half the body. Their color ranges from light red to dark lilac depending on the depth of the lesion below the surface, the density of the capillary bed, and the amount of cavernous tissue present. The skin of the face and the neck is most commonly involved. The tumors are of congenital origin, and once developed they seldom regress. Inflammation, ulceration, or thrombosis occasionally occurs.

Cavernous hemangiomas can be treated with irradiation, with very satisfactory results, particularly during the first year of life. Capillary hemangioma, however, do not respond as well to irradiation. The numerous other methods of treatment in vogue, such as electrocautery, the application of carbon dioxide

snow, and scarification tend to leave a conspicuous cicatrix. Surgical excision of the tumors is satisfactory but often technically impossible owing to the wide extent of the capillary mass.

Jönsson describes 17 cases of capillary hemangiomas treated by an exceedingly simple method which as regards the final cosmetic result he believes is quite satisfactory. Essentially his technique consists of destroying the capillaries in the surface layers of skin by abrasion while leaving the subcuticular tissues intact. The hemangioma is diffusely infiltrated with 1 per cent novocain and is rubbed directly with sterilized sandpaper taking care not to extend the rubbing beyond the tumor into normal skin, nor into the subcuticular tissues. Bleeding is profuse and pressure must be constantly applied during the procedure. All of the tumor may ordinarily be treated at one session. Infection must be scrupulously avoided, and the author prefers sulfathiazole ointment dressings. Complete healing occurs in about 10 days.

All cases of hemangioma are not equally well suited for this treatment, the dark red or bluish tumors respond much better than do lesions of a lighter color. Size is of no consequence but for a good result it seems necessary that the hemangioma can be emptied of blood by compression and stroking with the finger. Cavernous hemangiomas should not be treated by this method.

In a 2 year follow up, 13 of the cases showed good or completely satisfactory cosmetic results, and 4 cases showed only moderate improvement. Before and after photographs of 4 cases are included.

WYATT CAMERON, M.D.

Stuart, D. A. and Norwick I. Amebic Granuloma of the Skin. *Brit J S* 77: 947-948.

Amebic granuloma of the skin, or amebiasis cutis, an uncommon lesion due to infection with the *Endamoeba histolytica*, appears in the literature because of its rarity and interesting pathological and clinical picture. The *Endamoeba histolytica* may under certain conditions, invade the skin and cause extensive ulcerative granulomatous lesions. Blood stream in action has never been reported. The lesions arise by direct continuity via the lymphatics from some focus such as a drainage tract from the liver around a colostomy or from the rectum.

An unusual case report of amebiasis cutis of the buttocks is presented. A painful ulcerating lesion of the buttocks and posterior rectal wall was biopsied and ameba were found in the excised tissue. Because of contamination by the feces a proximal colostomy was done. The patient responded marvellously to emetine hydrochloride. Prior to the diagnosis of amebic infection the ulcerating lesion did not respond to the usual measures employed in perianal lesions. It is suggested that any acute ulcerative perianal lesion not responding to usual chemotherapeutic methods, be given a therapeutic test by emetine hydrochloride therapy and stool examination for the *Endamoeba histolytica*. The lesion is slightly raised with steep at times undermined, edges and surrounded by an

area of induration showing all signs of inflammation. The floor of the ulcer is covered with sloughing granulation tissue and is extremely painful and tender.

Macomber W. B. and Paletta, F. N.: Malignant Tumors of the Skin in Military Personnel. *Plast Reconstr Surg* 1947 2: 234.

Two hundred patients with malignant skin tumors were seen in a military hospital plastic service during a 3 year period. Seventy-eight per cent were in the second or third decades. The face was the site of the lesion in 92 per cent.

Three types of problems were presented: (1) reconstruction of a defect made in previous excision of the tumor; (2) removal of early malignant changes resulting from incompetent x-ray therapy; and (3) removal of tumors inadequately excised or which had received various forms of inadequate treatment.

The principles advocated include: (1) wide excision of all lesions; (2) closure directly by shifting of adjacent skin flaps or with skin grafts; (3) definitive reconstruction 6 months to 1 year after excision of large highly malignant lesions (after sufficient time has elapsed to be sure there is no persistent tumor); and (4) multiple excision after application of a temporary skin graft, if the defect warrants this.

Examples of various types of lesions of the forehead, eyebrow, eyelid, cheek, nose, lip, buccal mucous membrane, and ear, with 26 photographs and 10 drawings are presented.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Hoffman, William S. and Volini, Italo F.: Studies in the Oral Administration of Penicillin. Assays of Various Preparations and the Determination of the Effective Therapeutic Dose. *Am J Med Sc* 1947 213: 513.

The authors point out that it is an established fact that orally administered penicillin can produce therapeutic levels in spite of the fact that a portion of the penicillin is destroyed when it comes in contact with

gastric acid. A number of oral preparations were assayed in this study to determine an effective dosage.

Estimations of plasma penicillin concentrations were made with the *Bacillus subtilis* serial dilution method of Randall, Price, and Welch as modified by Hickey. Since it has been alleged that the *Bacillus subtilis* method is of doubtful value because of the presence of inhibitors in many penicillin free blood specimens, the authors took controls both from patients before the administration of penicillin and from untreated control patients. The authors were convinced that with their use of this assay method, possibly because of their use of citrated plasma, false positives would not ruin their study.

Since there is no agreement as to what plasma penicillin levels achieve therapeutic effectiveness, the authors accepted the empirical and established finding that 30,000 units every 3 hours, when given intramuscularly, were effective in most acute infections responsive to penicillin. Such injections give plasma levels of 0.5 unit per cubic centimeter at $\frac{1}{2}$ hour, 0.06 at $2\frac{1}{2}$ hours, and 0.03 at 3 hours.

A large variety of penicillin preparations were used with and without diluents, antiseptics, and buffers. On the whole, there was little difference in the statistical levels no matter which preparation was used. Crude penicillin alone in capsules produced almost the same values as did crude penicillin protected with pectin. Pure potassium penicillin gave levels not greatly different from potassium penicillin protected with a high melting fat. All forms when given in 100,000 unit doses after a priming dose of 200,000 units gave satisfactory levels for 3 or more hours.

Oral doses of 25,000 units were ineffective usually in producing appreciable plasma penicillin levels. 50,000 unit doses were also unsatisfactory.

Doses of 100,000 units when preceded by a primary dose of 200,000 units an hour earlier gave levels averaging higher than 0.125 unit per cubic centimeter for the first 2 hours and about 0.06 unit for the next 2 hours. Such levels were comparable with those obtained with intramuscular injections of 20,000 units every 3 hours. Doses of 200,000 units gave perceptible plasma levels even at 6 and 8 hours after the dose, although the levels achieved in the first hours were not significantly higher than the 100,000 units with the 200,000 unit priming doses.

From their findings the authors establish a therapeutic regimen of a primary dose of 200,000 units followed by 100,000 units of orally administered penicillin every 3 hours. This should produce therapeutic results in acute infections comparable to those resulting from the intramuscular dose of penicillin of 20,000 units every 3 hours.

SURGICAL PATHOLOGY AND DIAGNOSIS

Ellis, Frank: Needle Biopsy in the Clinical Diagnosis of Tumors. *Brit J Surg* 1947 34: 240.

The author outlines the following indications for needle biopsy: when a tumor lies deep to normal

skin or other tissues, when the possibility exists of the tumor being infected when a major operation would otherwise be necessary, and when such an operation would not allow of the successful extirpation of the tumor when the usual methods of obtaining histological evidence are contraindicated, and when excision of a lymph node is contemplated in a suspected case of Hodgkin's disease, needle biopsy may exclude cancer and may establish a diagnosis of Hodgkin's disease.

In 280 cases aspiration biopsies were carried out from the regional lymph glands, and in 87 cases from bones. The aspiration biopsy gave, on the average, about 63 per cent of useful results. In general, the type of case subjected to needle biopsy is one in which, because of lack of bed accommodation, lack of time or lack of adequate indication in the view of the clinician concerned, a biopsy would not be taken in the ordinary way. In other words, much of the evidence provided for the pathologist by needle biopsies would not be available at all if they were not done.

A drill type of biopsy is advocated for the following types of lesions:

1. Relatively superficial soft tissue lesions. These include cervical, axillary, inguinal, and other lymph nodes, breast lesions, muscle lesions, and lesions in such situations as the thyroid gland, parotid or other salivary glands, and the orbit.

2. Easily accessible bony lesions. These include lesions in all the bones except the vertebrae. The bone is inspected and carefully measured on the radiographs to determine the site of entry to be attempted by the drill aiming at an active part of the pathological process, and ease of approach.

3. The vertebrae. Obvious precautions are taken to avoid the vertebral artery in the cervical portion, the spinal cord and nerve roots. The dorsal and lumbar vertebrae are more difficult. The neural arches are easily accessible but not often affected. The bodies are deeply situated. From lateral radiographs taken with a marker on the skin in the mid

line, the depth (6 to 8 cm. usually) of the lesion from the skin can be measured. If the drill is then inserted through the skin at an equal distance from the midline at an angle of 45 degrees to the vertical with the patient lying prone, it is not difficult to strike the lesion. This procedure is best carried out under light general anesthesia and with facilities for radiographic verification of the position of the drill. Pentothal is adequate with premedication and efficient radiography. A grid used on the back for an anteroposterior radiograph with the patient supine is of aid in deciding the level at which to insert the drill through the skin.

4. Intrathoracic lesions. In a radiograph, the ribs form adequate markers for the chest, and by drawing lines from front to back it is possible to determine the direction in which the drill should be passed to the lesion.

5. Prostatic lesions. These are best dealt with in the lithotomy position. It is necessary to have the left index finger in the rectum. The needle is inserted through a small stab in the skin of the perineum, with the patient anesthetized (preferably a general anesthetic). The needle is easily felt, and can be guided into the prostate. The trocar is then removed and drilling commenced.

The author discusses at length the technique used in aspiration biopsy and drill biopsy. A review of the histological technique is also given. Many photographs showing the histological specimens from various locations are shown, which indicate the efficacy of these procedures.

The advantages of drill biopsy over aspiration biopsy are as follows:

1. The operator has greater control, not having to apply suction at the time of introducing the needle.

2. A larger piece of tissue is obtained which enables the pathologist to give a greater number of positive reports.

Both procedures may be carried out quickly, although the drill biopsy requires a more specialized apparatus.

THE ROIE OF VASCULAR SPASM IN RECOVERY OF STRANGULATED INTESTINE

Experimental Study

HAROLD LAUFMAN M.D., F.A.C.S. and HAROLD METHOD M.D. Chicago Illinois

MANY factors are involved in the recovery of intestine of question able viability once it has been released from strangulation. Some of these factors have been extensively investigated and will be reviewed in this report. One factor however which has received very little attention but which apparently is of significance in the recognition of viability and in the recoverability of strangulated intestine, is the degree of residual spasm in the involved vascular bed. It is therefore of rather fundamental importance to investigate the train of events in the intestinal vasculature following strangulation.

The present study is mainly concerned with two aspects of the problem. The first is the de-

velopment of a method of recognizing grossly the degree of vasospasm which might serve as an index to the recoverability of strangulated intestine. The second is an evaluation of present methods of resuscitation and an investigation into additional measures which could be of practical value. The importance of recognizing viable bowel and of resuscitating a borderline case to a state of viability are too well known to require emphasis at this time.

PATHOLOGICAL PHYSIOLOGY OF INTESTINAL STRANGULATION FROM THE STANDPOINT OF THE INVOLVED VASCULATURE

Strangulation of the intestine occurs when the blood supply of a closed loop obstruction has been compromised. Hence we are dealing with the combined effects of three pathological entities: closed loop intestinal obstruction, mesenteric vascular occlusion, and simple in-

terioles are almost empty and in severe spasm. The metarterioles and capillaries are in varying degrees of spasm and relaxation and the blood cells rock to and fro in some of them.

If the arterial occlusion continues, there is a gradual relaxation of the arteriolar side of the vascular bed under the influence of the local anoxia and some of the blood will settle back into the arteriolar vessels. Lewis observed this phenomenon in the upper extremity of man. If the occlusion continues long enough an equalization will finally occur in the distribution of the blood between the venous and arterial side. Grossly this is observed in the intestine under arterial strangulation by a gradual relaxation following the initial spasm pursuant to occlusion and a very slow but definite turn from a blanched, pale rippled appearance to a more homogenous cyanotic appearance. We have observed that if the occlusion remains long enough to allow this secondary relaxation to become evident grossly the chances for recovery diminish proportionately.

If an arterial type strangulation is released while some spasm remains in the intestinal musculature the blanched, spastic bowel becomes bright red and the small tight contractions give way to larger more organized peristaltic movements, but hyperactivity of the segment persists for some time (Fig. 2 frontispiece). In general the more prolonged the arterial occlusion the less pronounced will be this red response. Lewis noted this train of events in the human arm and termed the phenomenon reactive hyperemia. This has been defined as the period in which the local circulation to an organ is increased above the control resting level following the re-entry of blood into the ischemic tissue. During the period of occlusion the tissues have incurred a blood flow debt which is repaid as soon as possible after circulation is restored.

After the phase of reactive hyperemia in the intestine, there follows a secondary spasm of a mild nature which is apparently compensatory but which may be of importance in delaying eventual recovery of the bowel. If the strangulation remains until some secondary relaxation occurs the reactive hyperemia in the intestine is not so pronounced or it may be ab-

Fig. 1. Arterial type strangulation left, compared with venous type strangulation after 1 hour. There has been a slight relaxation in the blanched, rippled appearance of the arterial type by now but its mesentery is still free from petechiae and the bowel is pale, whereas the venous type strangulation is distended weeping and blood soaked.

sent. In such cases the color is violaceous due to the stagnation of blood in relaxed vessels.

The mechanism responsible for the spasm and vasorelaxation of blood vessels is as yet controversial. The spasm has been ascribed to stimulation of sympathetic fibers by the occlusive irritant while the relaxation is not dependent on the integrity of the sympathetic nerves but is apparently related to the accumulation of chemical products of tissue anoxia (17).

B Venous occlusion. In a venous type strangulation we are dealing with a loop which quickly becomes engorged, edematous and blood soaked (Fig. 1). Since most strangulations encountered at surgery are of the venous type and since it is a commonly acknowledged clinical fact that vasodilating measures such as warm packs do improve their appearance it would seem rather necessary that observations be made to clarify this point.

It has been shown that in the lower extremity when acute venous occlusion by a thrombus results in a damming up of blood and an increase in local venous and capillary pressure the magnitude of this alteration will be inversely proportional to the degree of available collateral circulation (31). It has been suggested (1) that the resistance (tone spasm?) in the walls of the minute vessels both on the arterial and venous sides tends to cause further decreased venous circulation. All the tissues including the capillary endothelium suffer from

anoxia, resulting in increased capillary permeability. Coincident with changes in arterial and venous portions of the system there is a diminution in the flow of lymph (31, 32).

Regarding the status of arterial blood flow in venous occlusion Abramson has summarized our present-day knowledge as follows:

Some workers have found an elevated cutaneous temperature and increased oscillometric readings while others have noted that the extremity is colder than normal. It may be that the same phase of the condition was not studied by the different authors or that the type of peripheral vascular response depends upon the magnitude and location of the site of occlusion. Other authors, notably Ochaner, are convinced that there is an unmistakable phase of arteriolar spasm following acute venous occlusions.

When binding tape is placed about a loop of intestine and its mesentery just snug enough to occlude the veins, the segment gradually becomes engorged and assumes a deep purple color. This is undoubtedly the result of damming up of blood in the veins and venules. Meanwhile, local arterial pulsations carry on in their usual manner and for a while are actually increased in intensity. This observation is in keeping with that of Lewis, who described an exaggerated pulse volume following venous congestion in the hand. Now if we allow the strangulation to continue we find that the arterial pulsations within the strangulated portion of mesentery become more feeble and as the tissue becomes more blood soaked arterial pulsations can no longer be palpated. Release of the strangulation at this point (about $\frac{1}{2}$ hour in short segments in the dog) will usually result in a resumption of the pulsations, a rapid disappearance of the deep cyanosis, and a bright red flush indicative of recovery of the bowel. Just before release capillary microscopy reveals engorged venules and quite narrowed arterioles. The capillary bed is very full, but not uniformly so. Extravasations of blood cells into the tissues are seen in every field. Variations of this condition can be seen up to about an hour of venous strangulation.

After approximately one hour of venous strangulation capillary microscopy reveals

not only the venules, but most of the capillary bed to be engorged and vessel walls are very difficult to distinguish because of the sanguineous extravasation into the tissue. The rate of blood flow through the arterioles has become markedly diminished and the blood cells travel in clumps. Minute thrombi form easily. Although the arterioles for the most part are narrower than the engorged venules there has been some relaxation by this time. As the blood is dammed up in the venous system the arterial stream becomes slowed. This process is by no means simultaneous or uniform in all areas. This secondary relaxation of the spastic arterioles in venous occlusion occurs sooner than in arterial occlusion. Nonetheless, it seems to bear the same relationship to recovery ability as in arterial occlusion. Thus the more pronounced the secondary arteriolar relaxation due to anoxia the poorer are the chances for recovery of circulation. Figure 3 frontispiece, illustrates a venous type strangulation after $2\frac{1}{2}$ hours. It is of very questionable viability.

In most instances a blood stained, plasma like transudate accumulates in the peritoneal cavity, the result of increased capillary permeability.

Arteriolar spasm in some venous strangulations may conceivably result from a tightening of the constriction due to tissue edema, finally to occlude the incarcerated arteries. In such a case we have a venous occlusion with superimposed arterial occlusion. However arteriolar spasm has been seen in pure venous occlusion without strangulation in which the main artery was free throughout the experiment.

If vasoospasm occurs in the early stages of venous strangulation increasing the arterial inflow by vasodilator therapy even in the presence of already overdistended veins should be of value provided the therapy is instituted while a sufficient degree of tone remains.

In general whether the strangulation be arterial or venous the prognosis for recovery is apparently inversely proportional to the degree of secondary relaxation. In venous occlusion there is undoubtedly a changing balance between the residual tone in the smaller vessels on the one hand and the relaxation caused by anoxia or distention resulting from engorgement on the other.

Fig. 4. a, left, Method of taking surface temperature of intestinal loop during strangulation. b, Same procedure

after release of strangulation. These readings are valid only when compared with similarly exposed normal bowel.

EXPERIMENTAL METHODS

Experimental inquiry into the clinical application of the status of the minute vessels in strangulation requires an appropriate gross measuring device. We therefore borrowed a test which has long been used in peripheral vascular disease—that of recording skin temperatures—and applied it to the serosal surface of the bowel.

Ordinary mongrel dogs were starved for 24 hours and anesthetized with intravenous nembutal. All strangulations were produced by placing binding tape about a loop of ileum. The strangulated segment was always about 8 centimeters (roughly 3 inches) long. The venous type strangulations were made by tying the tape just tightly enough to occlude the veins to the segment but allowing arterial pulsations to come through. The bowel immediately turned purple-blue then gradually distended. In the arterial type strangulations the tape was tightened until no pulsations could be felt in the vasa recta. We could determine the completeness of an arterial type strangulation by the blanched, rippled spastic appearance of the gut musculature. In preliminary experiments we found that a segment about 3 inches long was convenient in that it showed questionable viability after approximately 1 hour for the venous type and after $2\frac{1}{2}$ hours for the arterial type. After strangulation the loops were returned to the abdomen until time for recording surface temperatures.

Surface temperatures were taken with an ordinary skin thermometer¹ by placing the thermometer on the lateral serosal surface of the bowel and keeping it in place until the mercury came to a standstill (Fig. 4). This usually occurred after $\frac{1}{2}$ to $1\frac{1}{2}$ minutes. Preliminary work indicated that variations up to 0.6 degree C may fall within experimental error but after repeated performances this error could be reduced almost to zero. Since the intestinal surface temperature is influenced by the temperature and humidity of the air, a control reading of neighboring normal bowel similarly exposed was always made just before that of the involved segment. Ideally surface temperatures should be taken on dry surfaces. When two points are being compared however it is more important that both should be exposed to the same conditions. To equalize the variables associated with loss of heat by evaporation readings were always taken when the bowel was moist. In this way the difference in the degree of evaporation heat loss between the control and the involved loops was brought within satisfactory limits for our purposes. The bowel was always held in the same manner to equalize errors induced by conduction. Thus by subjecting the normal control bowel and the involved loop to the same errors of heat loss through vaporization, radiation, convection and conduction our readings

¹Both the Becton Dickinson and Rauscher Betrolde skin thermometers were used.

Chart 1. Temperature curves in viable venous type strangulations, above, compared with those in nonviable strangulations of the same type, below. Temperature of strangulated loop shown by solid line; control by interrupted line. S, Strangulation; R, release. Note that the duration of strangulation varies with each segment and although important within limits, does not alone determine the type of temperature response, because of the many other factors involved. These graphs indicate that if the temperature response following the release of strangulation is poor or negative the viability of the loop is very doubtful.

could be interpreted as being accurate on a comparative basis between the two points. It was not necessary to obtain absolute readings by calculation or to use an electrical thermocouple.

INTESTINAL SURFACE TEMPERATURE IN VENOUS TYPE STRANGULATIONS

Temperature readings were made before and after release in 28 venous type strangulations. Typical curves of the surface temperature are portrayed in Chart 1. Shortly after strangulation the temperature of the loop rose slightly above that of the neighboring normal bowel in some instances. This undoubtedly was the result of initial engorgement. After 45 to 90 minutes of strangulation the temperature of the loop dropped from 1 to 5 degrees centigrade. Upon release of the strangulation we were interested in determining whether the behavior of the surface temperature was an indication as to whether or not the segment would survive. Three minutes were allowed to elapse between the time of release and the next reading and an equal time interval between subsequent readings. We found that in the viable segments there was a slow rise in temperature sometimes finally reaching that of the neighboring normal bowel other times not quite

equalling the control reading. In nonviable segments the temperature either remained at its strangulation temperature or actually declined. No resuscitative therapy was used in these animals. Our predictions were checked by postmortem examinations when necessary.

INTESTINAL SURFACE TEMPERATURE IN ARTERIAL TYPE STRANGULATIONS

Temperature readings in 20 arterial type strangulations showed a rather different response than did the venous types. The temperature began to drop almost immediately, first slowly then more rapidly. As shown in Chart 2 temperatures dropped as much as 6 degrees after arterial occlusion. However if the strangulation was released before the phase of secondary relaxation that is, up to about $1\frac{1}{2}$ hours for the length segment we were using the temperature bounced up to above that of the neighboring normal bowel. This rebound or reactive hyperemia was never observed in venous type occlusions.

If the strangulation was allowed to remain until after secondary relaxation of the intestinal musculature, reactive hyperemia did not occur and the temperature stayed at its strangulation level. Such segments were always nonviable.

Chart 2: Temperature curves in viable arterial type strangulations showing the phenomenon of reactive hyperemia as it reflects in the temperature response following release. If an arterial type strangulation is nonviable, its temperature curve is no different from that of a nonviable venous type as shown in Chart 1.

METHODS OF RECOGNITION AND REVIVAL OF BORDERLINE CASES OF INTESTINAL VIABILITY

Oftentimes recognition of viability may prove fallacious even by surgeons of the widest experience. The tests for viability in use today include (1) the return of pulsations to the segment (2) the return of the pink color of viability (3) the return of peristaltic movement (4) the fluorescein test. Although all these tests are of value, they have certain limitations.

The return of pulsations may not always be an indication of viability. Pulsations may not be palpable yet the segment may live. Pulsations are known to be transmitted through thrombotic vessels. Furthermore, in venous occlusions with irreversible changes in the bowel the return of pulsations may be misleading.

The return of color resembling that of viability is not always useful as a test since many segments with an ominous deep purple hue are known to survive. However when the blush of viability does return it is a fairly reliable criterion.

The return of peristalsis is a poor prognostic criterion of viability since we know that anoxic intestine may be very active for a while. This anoxic spasm may be erroneously interpreted as active peristalsis.

The fluorescein test first employed by Lange and Boyd in 1942 is probably the best test of viability we have to date. It is unquestionably accurate (15) but has its drawbacks. We think it a fair assumption that most surgeons would rather go ahead and resect a questionable segment of bowel than darken the operating room, use a special ultraviolet lamp with a Wood filter and inject a solution of fluorescein and sodium bicarbonate intravenously into the patient.

Recent developments in isotopic tracer substances fire the imagination with possibilities of using them in determining viability of bowel. The lead encasements, Geiger counters and other necessary paraphernalia might make the method cumbersome, however.

Thus there is need for a simpler, more direct, less cumbersome test for viability of the intestine.

As a rule tests for viability are employed after various therapeutic measures have been tried to revive the questionable bowel. Therapeutic approaches to the revival of bowel just released from strangulation can be listed as follows: (1) the application of hot packs to the bowel (2) inhalation of pure oxygen (3) injections of procaine hydrochloride into the mesentery near the vessels of the segment (4) the use of heparin to prevent propagation of thrombi and to decrease the viscosity of the blood. Each of these measures carries its own drawbacks.

Hot packs may not only damage the serosal surface and thus lead to adhesions but they actually enhance thrombosis in the superficial mesenteric veins close to the segment. However it is well known that mild heat acts as an active vasodilator. Temperatures above 34 degrees C usually exceed that of normal exposed bowel and can therefore be termed warm. Lewis has shown that temperatures of over 47 degrees C may cause tissue damage and even thrombosis.

The inhalation of oxygen for purposes of enhancing the recovery of strangulated bowel was introduced by Chase some 20 years ago. It is true that circulating blood takes on a bright red color after oxygen inhalation and therefore any normal tissue it traverses is similarly affected. However there is no physio-

Chart 4. Further comparison of typical temperature curves following various forms of resuscitative therapy. The combined effect of all four therapeutic measures is apparently of greatest value.

by experiment. Some of the evidence on the beneficial effects of this drug in peripheral vascular disease has been equivocal and in several reports it has been shown to be of no value (24). Apparently the nature of the local pathology and the degree of tone remaining in the blood vessels has much to do with the success or failure of the drug. Furthermore dosages have never been uniform and its action is relatively short lived. Experimental studies on the value of papaverine in the resuscitation of strangulated bowel have not been previously reported to our knowledge.

In preliminary experiments we tested the effects of papaverine by responses in the gross color of strangulated loops. Next, we employed surface temperature readings as a more refined test of its efficacy. Finally the effect of papaverine was studied in comparison with that of well known measures now in use, in order to determine a means of obtaining the maximal response to therapy.

PRELIMINARY EXPERIMENTS ON THE EFFECT OF PAPAVERINE HYDROCHLORIDE ON THE GROSS APPEARANCE OF STRANGULATED INTESTINE

In order to eliminate the question of subjective impressions of color change, color pho-

tography was employed. In each experiment two dogs of about equal weight (7 kilos) were anesthetized with intravenous nembutal after a 24 hour starvation period. Every attempt was made to produce precisely the same type of strangulation in each of the 2 dogs. Venous type strangulations were made with binding tape for equal periods of time before release. Among the variables which required standardization were the tightness of the strangulating tape and the anatomical location of the loop. Even in dogs starved for 24 hours the amount of intestinal contents may vary. To obviate this variable, only those segments which upon release appeared identical to their control counterparts were used for testing the effects of papaverine.

Two speed graphic cameras with identical lens corrections were set up under identical lighting conditions and identical exposure factors. One dog served as a control and received no therapy after the strangulations were released while the other dog received a slow injection of $\frac{1}{2}$ grain¹ of papaverine hydrochloride.

A 1 cubic centimeter ampul of papaverine contains $\frac{1}{4}$ gr. (0.031 gm.) of active principle. This is a relatively large dose, equivalent to 0.045 gm. per kilogram. Blood pressure studies in previous experiments using this dose revealed a transient (3-minute) drop in blood pressure and a fleeting stimulation of respiration from which all dogs recovered with no ill effects. We found that papaverine had a negligible effect on intestinal motility.

ride into the femoral vein 3 minutes after the release of each segment. The strangulations were released at $\frac{1}{2}$ hour intervals, from $\frac{1}{2}$ to 3 hours after initial strangulation. Photographs were taken of the released loop in each dog 3 minutes after papaverine was injected (Figs. 5 6 7 frontispiece).

The photographs gave us the impression that papaverine definitely improved the color response of the bowel following strangulation up to about $1\frac{1}{2}$ hours of strangulation. It must be remembered that in longer loops the time factor is considerably lengthened. After 2 hours of venous type strangulation no recovery could be seen in either treated or control loops (Fig. 8 frontispiece). Three inch loops in dogs subjected to venous type strangulations for more than $1\frac{1}{2}$ hours are usually beyond recovery under any circumstances.

SURFACE TEMPERATURE CHANGES IN INTESTINAL LOOPS OF QUESTIONABLE VIABILITY FOLLOWING PAPAVERINE HYDROCHLORIDE AND OTHER RESUSCITATIVE MEASURES

Strangulations of both the venous and arterial types were produced in the manner mentioned previously. The strangulations were left in place for varying periods of time until the loop reached a stage of questionable viability. Surface temperatures were recorded while the strangulation was still in place and compared with a control reading of normal bowel. After release of the strangulation temperatures were again taken following a lapse of 3 minutes. One group was treated with hot packs for 3 minutes, a second group received an injection of novocain perivascularly into the mesentery, a third group was given inhalations of pure oxygen, and a fourth group received 1 cubic centimeter of papaverine hydrochloride in a peripheral vein by slow injection. The effect of these procedures and various combinations of them on surface temperature was observed. A prediction was made in each case as to the viability of the segment and its accuracy checked by autopsy examination.

COMPARATIVE ANALYSIS OF METHODS OF RESUSCITATION OF STRANGULATED INTESTINE

The number of strangulated loops subjected to the various forms of therapy is small since

we chose only those of very questionable viability. Such a study contains many variables and is rather difficult to control for purposes of accurate quantitative comparison. Thus, we were satisfied to determine in a qualitative manner whether a given therapeutic measure caused a favorable response or not.

After the strangulation was released for 3 minutes and the temperature recorded, treatment was instituted and temperatures checked at 3 minute intervals up to 36 minutes in some instances. The forms of treatment included warm packs locally, papaverine hydrochloride intravenously, procaine hydrochloride injections into the mesentery, oxygen inhalations, and various combinations of these measures. Typical temperature responses are shown in Charts 3 and 4.

We found that in most instances, each of these measures has some merit, and there is no reason why all of them should not be employed. However their effects are not necessarily mathematically cumulative.

VALUE OF PAPAVERINE AS AN ADJUNCTIVE FORM OF THERAPY

In general, we found that the most consistent rises in temperature resulted when papaverine hydrochloride was used in addition to one or several of the other resuscitative measures. For example, when warm packs were applied to the segment after its temperature stabilized there resulted a temporary rise. Three minutes later however there was a decline in temperature. If then papaverine was injected, the temperature rose and held a more or less constant level. Such a loop was considered viable. If the papaverine gave little or no response, the loop was declared nonviable.

Oxygen inhalations alone gave only a moderate response in temperature in 12 loops. Although the color seemed to improve in some cases, it by no means did so in every instance. If the segment was still viable, the intravenous injection of papaverine even 30 minutes after the inhalation of oxygen resulted in a substantial rise in temperature, often equalling that of the adjacent normal bowel.

Perivascular injections of procaine hydrochloride into the mesentery were made in 7 instances. They produced little or no response

when used alone, but when papaverine was injected intravenously the rise in temperature was definite provided the loop was recoverable. We could not determine whether this was the combined effect or the effect of papaverine alone since the response to papaverine varied from case to case.

When papaverine alone was used the temperature of the loop if it was recoverable, rose in each of 15 instances. However in several instances the temperature could be boosted further by adding another measure, such as warm packs. We did not administer the drug postoperatively in any of our animals although this might be advisable clinically.

ACCURACY OF SURFACE TEMPERATURE AS A TEST OF VIABILITY

Our predictions of viability based solely on surface temperature responses in over 50 strangulations were correct in every instance but two. These two segments each in a different animal, were found intussuscepted at post mortem. Our presumption was that after regaining viability they were reestranged by intussusception after the abdomen was closed and had they not intussuscepted they would have survived. We therefore thought of the test as one which might be of some clinical value.

SUMMARY AND CONCLUSIONS

The recovery of strangulated intestine has been investigated from the standpoint of the behavior of the involved vasculature. Evidence obtained by intestinal surface temperature readings indicates that there is considerable residual vasospasm in the minute vessels of a still viable loop. Of the many factors which affect the recoverability of strangulated intestine vasospasm is of no small significance whether the strangulation be primarily arterial or venous.

The gross appearance of a still viable arterial type strangulation is markedly different from that of a still viable venous type strangulation. By the time an arterial strangulation assumes the gross appearance of a venous type, its vasculature has lost all reactivity and is beyond recovery. However an arterial type strangulation retains recoverability more than 5 times as long as does the venous type.

Release of a viable arterial type strangulation results in reactive hyperemia followed by a phase of vasospasm, as demonstrated by intestinal surface temperature readings. Release of a viable venous type strangulation is followed by a slow rise in temperature to the control level or not quite reaching it. This latter phenomenon might conceivably be due to the following acting separately or in combination: (1) the necessity of the renewed blood flow to move the stagnant venous blood through engorged veins (2) the formation of thrombi causing a rerouting of circulating blood through fewer channels (3) arteriolar spasm due to secondary arterial occlusion which may follow venous occlusion (4) reflex arteriolar spasm following pure venous occlusion.

In nonviable segments of either type release of the strangulation results in a poor temperature response or an actual decline in temperature. As secondary relaxation of the vasculature progresses during strangulation there is a loss in reactivity to resuscitative measures.

The response of intestinal surface temperature to the various forms of resuscitative therapy is offered as a simple test for viability which may have some clinical application. The rise in temperature of the affected loop as compared to normal bowel is an indication as to its recoverability.

Papaverine hydrochloride is of value in releasing residual vasospasm thus aiding the recovery of bowel following strangulation provided the loop is recoverable. Comparative studies between the effects of warm packs oxygen inhalations mesenteric novocain injections and the intravenous administration of papaverine were attempted. All these measures were found to have some value in increasing the blood flow through a still viable loop of intestine. When papaverine in large doses was given following one or a combination of the first three measures an additional response was usually seen.

SURGICAL TREATMENT FOR SYMPTOMS PRODUCED BY CERVICAL RIBS AND THE SCALENUS ANTICUS MUSCLE

ALFRED W ADSON M.D F.A.C.S Rochester Minnesota

TWENTY TWO years of experience in the treatment of symptoms produced by cervical ribs and the scalenus anticus muscle have revealed many interesting facts. Section of the scalenus anticus muscle which I suggested and reported on in 1927 instead of removal of the supernumerary rib continues to be the operation of choice (1 2) Occasionally a portion of a completely formed cervical rib has to be cut away with rongeurs to mobilize thoroughly and relieve all irritation on the brachial plexus, in addition to sectioning of the distal end of the scalenus anticus muscle. Cervicothoracic sympathectomy occasionally has to be performed in conjunction with scalenotomy when vascular and vasomotor symptoms predominate. An anomalous formation of the first rib with the presence of a cervical rib requires resection to liberate thoroughly the brachial plexus.

THE VASCULAR TEST

I should like to re-emphasize the importance of the vascular test (3) a maneuver to which other authors have attached my name. The test indicates whether or not the volume of the pulse has been altered suggesting that the subclavian artery has or has not been compressed. If the subclavian artery has been compressed there is a strong supposition that the brachial plexus also is irritated whenever the scalenus anticus muscle is placed on tension the artery being displaced posteriorly against trunks of the plexus. The test consists of having the patient take a long breath elevate his chin and turn it to the affected side (Fig 1a and b Fig 2a and b) This is done as the patient is seated upright, with his arms resting on his knees. An alteration or obliteration of the radial pulse or change in blood pressure is a pathognomonic sign of a scalenus anticus syndrome. Since I called attention to

this phenomenon in 1927 it has been too often overlooked in a surgeon's desire to operate for pain in the shoulder and arm supposedly due to the syndrome

It has been my experience that little has been accomplished by the scalenotomy procedure for the scalenus anticus syndrome without the presence of cervical ribs or unusually large transverse cervical processes unless the result of the vascular test is positive. The test for muscle tenderness and nerve block advocated by Ochsner Gage and DeBaKey apparently has proved extremely valuable in the selection of patients for surgery when a syndrome of scalenus anticus is considered.

The vascular test has other diagnostic values such as determination of the presence or absence of subclavian arterial constriction without symptoms when cervical ribs are identified roentgenologically by accident. If the result of the test is negative surgical treatment is not indicated and the patient should not be told of the finding. If the result of the test is positive, surgery has to be considered then or later depending on how much constriction has taken place. If the radial pulse can be obliterated scalenotomy should be performed at once, since I have observed on several occasions atheromatous thickening in the wall of the subclavian artery under the scalenus muscle where friction existed. In 2 patients of mine the artery ruptured at the site of the atheromatous patch after scalenotomy. In one patient, it occurred 12 days after surgery. The hemorrhage was so extensive that the patient died before I could bring him back to the operating room and ligate the subclavian artery. In the second case it occurred just as I had finished the operation. I promptly exposed and ligated the proximal end of the artery. The entire wall of the vessel was brittle in that portion of the subclavian artery that lies posterior to the scalenus anticus muscle. Fortunately the patient recovered without

Fig. The vascular test a, the subclavian and radial arteries identified, b, pulsations of arteries obliterated by inspiration, elevation of patient's chest and rotation of his head to the affected side. In this case, the left.

complications, and was also relieved of symptoms.

TAUT OMOHYOID MUSCLE

The omohyoid muscle in people with long necks not infrequently compresses the brachial plexus and gives rise to paresthesias. Although this muscle usually is divided during the operation I have purposely left the ends unsutured in several cases. I have done this after an experience with a patient who had undergone scalenotomy elsewhere for the syndrome this patient also had a small cervical rib. Not being sure that the scalenus anticus muscle had been completely divided, I advised reoperation. I found everything to be satisfactory except that the omohyoid muscle was very tense and acted as a band running diagonally across the brachial plexus. I divided the muscle and closed the wound. The patient was relieved of her symptoms of paresthesia of the lower arm and hand.

DEVELOPMENT OF SUPERNUMERARY RIBS

Jones attributed the embryologic formation of supernumerary ribs to a conflict between forming plexuses and ribs. In higher forms, the limb buds cover several vertebral segments, the nerves from which grow into the buds. However the diametric growth of the limb buds does not keep pace with the longitudinal growth of the vertebral column and soon segmental nerves have to pursue an

oblique course to enter the buds. Then begins the conflict between the obliquely running nerves and the newly forming ribs. The embryonic nerve trunks are far larger in proportion to the vertebrae and ribs in the embryo than in the fully developed animal. The obliquely running nerves normally impede the growth of the ribs, so discouraging them that they merely form vertebral processes. Todd was of the opinion that the vessels have equal importance with the nerves as causative factors in modification of the upper end of the thorax.

The reported anomalies of the upper end of the thorax run from rudimentary first ribs to double cervical ribs on the same side (5 24 25).

Gruber in 1869 classified cervical ribs. He divided them into four groups according to extent of growth (Figs. 3 and 4) (1) a rib of slight degree reaching beyond the transverse process (2) a more advanced rib reaching beyond the transverse process, either with a free end or touching the first rib (3) an almost complete rib the connection with the cartilage of the first rib being formed by means of a distinct band or by the end of the long body of the cervical rib and (4) a complete rib possessed of a true cartilage which unites with the cartilage of the first rib (Fig. 5).

The surgical anatomy of cervical rib is essentially that of the posterior triangle of the

Fig. 2. The vascular test, a, appearance of the anatomic structures when the scalenus anticus muscle is relaxed; b, constriction of the subclavian artery and brachial plexus when the scalenus anticus muscle is contracted.

neck. The posterior triangle curves obliquely around the lateral aspect of the neck. It is bound in front by the sternomastoid, behind by the trapezius, while its base is formed by the middle third of the clavicle. Its floor is formed from above downward by the splenius capitis, levator scapulae, scalenus medius, and posticus muscles, the first rib and the first digitation of the serratus magnus. The scalenus anticus muscle does not form a part of the posterior triangle since it is directly behind the clavicular portion of the sternomastoid muscle (31).

Todd (47-49) believed that the scalenus and intercostal muscles arise from the same muscle plane, forming two sheets, the outer forming the scalenus anticus and minimus muscles, the inner the scalenus medius and posticus muscles. These sheets of muscles are continued as the internal and external intercostal muscles. The subdivisions of the scalenus muscles are made by the passage of vessels and nerves. The course of the subclavian artery through the scalenus muscles corresponds to that of an intercostal artery through the wall of the thorax.

The contents of the posterior triangle are (1) arteries—the third part of the subclavian, the transverse cervical and suprascapular; (2) veins—the subclavian and external jugular; and (3) nerves—the brachial plexus.

The subclavian artery is divided into three parts by the scalenus anticus muscle. The

first part is medial to the muscle, the second part directly behind and the third part is lateral. The subclavian vein is below and in front of its artery with the scalenus anticus muscle lying between. The phrenic nerve passes downward in front of the scalenus anticus muscle toward the medial border. The cervical pleura is directly below and behind the first and second parts of the subclavian artery. It extends higher in the neck in the case of persons with cervical rib. An important relationship to the first part of the subclavian artery on the left side is the thoracic duct which arches down in front of it in order to end at the junction of the internal jugular and subclavian veins. The first rib is below the third part of the subclavian artery.

INCIDENCE OF SUPERNUMERARY RIBS

To determine the incidence of cervical ribs, a study was made of roentgenologic findings in a complete series of patients registered at the Mayo Clinic between given dates. The study was made before 1927 when fewer roentgenograms were made of the cervicothoracic portion of the spinal column than are made today. The study showed that 303 patients had cervical ribs, an incidence of 0.0563 per cent, or 5.6 patients per thousand. Of these 303 patients, 84 were males and 219 were females. Roentgen-ray examination revealed bilateral cervical ribs in 143, a cervical rib on the right side in 70 and a cervical rib on the left side in

90 cases. In cases of unilateral cervical rib there frequently existed on the opposite side a supernumerary costal tubercle which did not extend beyond the transverse process of the cervical vertebra and was, therefore, not classified as a cervical rib. It might easily have been placed in Gruber's first class. In 167 cases of the group of 303 the presence of cervical ribs was discovered accidentally because there were no symptoms (19). Thus, 55 per cent of the patients were symptom free. Of the remaining 136 patients, only 36 were operated on before 1928 (23) among the others the symptoms were mild or too indefinite to justify surgical treatment. However in view of the added information now obtainable by the vascular test and in view of the observations I have made while performing scalenotomy subsequently I suspect that a larger percentage of patients should have had surgical treatment.

White and associates, in a study of congenital malformations of the first thoracic rib revealed some interesting data concerning the incidence of malformations and the similarity between the symptoms of malformations and those resulting from cervical ribs. He quoted Haven, who reviewed 5 000 routine roentgenograms of the thorax in which he found 38 abnormalities of the first thoracic ribs as compared with 37 cervical ribs. His findings of cervical ribs represented an incidence of 0.074 per cent or 7.4 persons with cervical ribs per 1 000 (7, 9, 13, 40). These figures slightly exceeded ours.

ETIOLOGIC FACTORS

Authors attempting to explain the mechanism responsible for the symptoms associated with cervical ribs or for the symptoms developing without the presence of cervical ribs have contributed numerous reports of cases, with peculiarities in this or that case.

There are several factors that play important roles in the production of the symptoms. Probably no one factor is responsible for all the symptoms, although some are more responsible than others. It is difficult to explain why all patients with completely formed cervical ribs do not have symptoms. It is just as difficult to explain why symptoms develop

in so few of these cases when it is considered that the shoulder girdle has a tendency to descend as all people become older. There must be a good reason why the symptoms develop in early adult life and rarely in childhood. It is not so difficult to understand why vascular phenomena and vasomotor disturbances arise, other than the fusiform aneurysm which only rarely develops in the third portion of the subclavian artery lateral to the outer border of the scalenus anticus muscle.

I believe there are three factors responsible for the symptoms, with the scalenus anticus muscle being the chief one. The first factor is that those persons in whom symptoms develop have an anatomic structure of the neck which is different from that of normal persons. The cervical portion of the spinal column is longer and this same congenital defect accounts for the high-lying second division of the subclavian artery. The base of the posterior cervical triangle which runs parallel with the superior border of the clavicle is shortened. The width of the base, and the distance between the posterior surfaces, of the scalenus anticus and the scalenus medius and posticus muscles likewise are congenitally shorter or perhaps it should be called lower so that the space through which the subclavian artery and the cords of the brachial plexus must pass is decreased. Then, if there is present a cervical rib or a large cervical transverse vertebral process, the structures passing through the base of the triangle are still further compressed, since the bony structures elevate the floor and displace the plexus forward against the subclavian artery. The subclavian artery is unable to dislodge itself and, therefore, is caught, compressed, and irritated between the brachial plexus from behind and the scalenus anticus muscle in front.

I have also observed that in cases in which circulatory disturbances and brachial symptoms are associated and are severe, the insertion of the scalenus anticus muscle invariably is wide, the muscle being reflected laterally beyond the operculum of the first rib. This narrows the space between the lateral border of the scalenus anticus muscle and the cervical rib and accounts for additional compression of the brachial plexus and the subclavian artery.

The second factor which is concerned more with the onset of symptoms probably is associated with the descent of the shoulder girdle (6) This process begins in early adult life. The descent or sagging of the shoulders possibly could add sufficient traction on the brachial cords to precipitate symptoms when the congenital abnormality of the lower part of the neck had already reduced the normal freedom of movement.

I wish to report a number of observations to support my opinion that the scalenus anticus muscle the third and chief factor was the one chiefly responsible for the symptoms (10 37 42)

My attention was called to the possible rôle the scalenus anticus muscle played in the cervical rib syndrome on June 13 1925 when I was asked to examine a patient who had gangrene of the first and second fingers of his right hand It was known that he had a cervical rib on the right side but we were unable to explain the unilateral vascular changes in the fingers. The brachial radial, and ulnar arteries had no pulsations. The right hand and lower part of the arm were cyanotic cold and moist In view of my interest in vasomotor disturbances, I advised surgical exploration of the cervical rib This was done I used the anterior approach that I still use—the one in which the base of the posterior cervical triangle is explored through a unilateral collar skin incision After reflecting the clavicular portion of the sternocleidomastoid muscle I exposed the scalenus anticus muscle.

Fig. 3. A completely formed right cervical rib which is producing symptoms, and an incompletely formed cervical rib on the left which is not producing symptoms.

Fig. 4. Surgical specimens of cervical ribs, illustrating the different sizes and shapes under Gruber's classification a, group 2 b, group 3 c, group 4.

The muscle was in my way as I explored the cervical rib so I proceeded to section the costal attachment I noticed that with each inspiration of the patient the scalenus anticus muscle bulged and became tense and completely collapsed the subclavian artery After I had divided the muscle there remained an indentation where the muscle had rubbed the artery This indented portion of the artery was shell like to palpation for a calcareous atheroma had developed there The vessel did not give way at the site of this atheroma, as it did in the 2 other cases to which I have referred

After sectioning the scalenus anticus muscle I continued the dissection I was impressed by the damage that had been done to the artery When the artery was released from the pressure of the muscle it began to slip back into the thorax and as it did so it released the brachial plexus. Hence the brachial plexus no longer was jammed over against the cervical rib It was apparent that removal of the cervical rib would have been insufficient to relieve the constriction of the subclavian artery It likewise was apparent that sectioning of the scalenus anticus muscle which promptly contracted upward relieved the situation and would have done so without removal of the cervical rib However I proceeded to remove the cervical rib by the anterior approach, since in all surgical teaching up to that time removal of cervical ribs had been the practice advocated

After having several similar experiences, I became convinced that it was not necessary to remove cervical ribs routinely and that the chief etiologic element was the scalenus anticus muscle. This point was further substantiated by experience with the vascular test. During the operation I could increase the tension on the scalenus anticus muscle by having the anesthetist elevate the patient's chin and rotate the head to the affected side. The increased tension increased the pressure and further collapsed the subclavian artery with each inspiration. It was also observed in employment of the test preoperatively that the more completely the circulation was obliterated at the wrist the greater was the evidence of arterial compression when the subclavian artery was exposed during the operative procedure.

The explanations vary somewhat as to why the symptoms begin in early adult life. Descent of the shoulder girdle may be one of the contributing factors. I have always held that this process occurred at the height of muscular development which would explain the hypertrophy of the scalenus anticus muscle. Although both of these factors—descent of the shoulder girdle and hypertrophy of the scalenus anticus muscle—may contribute to the mechanism I have never been called on to operate on athletes, wrestlers, boxers or football players with marked muscular hypertrophy or with heavy descending shoulders. Perhaps the person who has these congenital anomalies learned early in life that it was painful to pursue vigorous activity and therefore avoided athletics.

We still have failed to explain why the scalenus anticus muscle has hypertrophied in so many cases. It is possible that the muscle, with other accessory respiratory muscles is called on to lift a heavier load during respiration in adult persons than in children because the shoulders and pectoral girdle have increased in weight.

I believe the scalenus anticus syndrome which develops with or without cervical ribs results from a combination of factors. First, the congenital anomaly restricts the activity and freedom of movement of the brachial plexus and the subclavian artery. As long as

no activating factor is introduced, the artery may be compressed slightly with each inspiration without the production of symptoms. But as the load on the scalenus anticus muscle is increased the artery is compressed and displaced backward, jamming the plexus against the floor the cervical rib or the transverse process of the cervical vertebra. All this varies in degree depending on the room within the base of the posterior triangle of the neck. The neurologic symptoms depend on the nerve trunk involved and the degree of pressure applied. The atheromatous changes of the subclavian artery with resulting thrombosis and occlusion no doubt are due to local damage and a liberated embolus. The degree of damage bears a direct relationship to the trauma. The presence of adhesions about the subclavian artery suggests thrombosis of the vasa vasorum and an inflammatory reaction. The tenderness of the scalenus anticus muscle that Gage has brought to our attention probably is caused by thrombosis of arterioles from pressure trauma within the muscle. It undoubtedly gives rise to a local inflammatory process and sensations of pain which Gage said he could temporarily relieve with a local anesthetic agent.

The vasomotor phenomenon results from stimulation of the fibers as they pass, intermingled with the myelinated nerve fibers of the brachial trunks. In the patients who present an unusual vasomotor disturbance the sympathetic nerve distribution probably is as Telford and Stopford suggest. They in reviewing a number of dissecting room subjects without cervical rib found that the lower trunk of the brachial plexus in 8 cadavers lay on the upper surface of the first rib. In the eighth cadaver they found that in the inferior part of the lower trunk of the brachial plexus there was a distinct and separate bunch of unmyelinated fibers which they interpreted as being sympathetic fibers passing to the upper limb by the way of the lower trunk and which had not yet become incorporated with and intermingled among the other fibers of the lower trunk. The fusion of the sympathetic fibers with the lower trunk was, in this instance at a more distal point than usual. It is my impression that a similar situation occurs now and

Fig. 5. a, A cervical rib with a fibrous band between the cervical rib and the thoracic rib such a cervical rib does not produce symptoms because there is ample space between the lateral border of the scalenus anticus muscle and the ligamentous band of the cervical rib b, compression of the lower trunk of the brachial plexus by pressure of the scalenus anticus muscle against the fibrous band, b relief of compression obtained by tenotomy of the scalenus anticus muscle and division of the fibrous band c, compression of the lower trunk of the brachial plexus by pressure of the scalenus anticus muscle against the completely formed cervical rib c' relief of compression obtained by either tenotomy of the muscle or resection of the rib d, compression of the lower trunk of the brachial plexus and the subclavian artery against the completely formed cervical rib d relief of compression achieved by tenotomy of the scalenus anticus muscle or by resection of the cervical rib.

then when cervical ribs are present because the vasomotor symptoms of vasospasm and hyperhidrosis predominate and are out of proportion to other neurologic findings, so that major involvement of postganglionic sympathetic fibers is suggested

Telford and Stopford (44) further wrote that in the presence of a cervical rib the cervical sympathetic fibers are more likely to be irritated than would be true if the rib were not present. This point is substantiated in that the vasomotor phenomena are less marked in the scalenus anticus syndrome when cervical ribs are absent than when they are present.

In discussing the influence of irritation of the sympathetic nerves Telford and Stopford said it is their opinion that the irritation produces enough spasm of the vasa vasorum to

result in constriction and obliteration of the vessels, with resulting nutritional changes in the larger arterial walls which ultimately might lead to thrombosis. I presume it is possible that this process of thrombosis of the vasa vasorum and impairment of the arterial wall may account for the development of the fusiform aneurysm in the third portion of the subclavian artery lateral to the scalenus anticus muscle. It is a common occurrence to see that the third portion of the subclavian artery is much larger in diameter than the first portion which is medial to the scalenus anticus muscle. I have always attributed this to paralysis of the vasomotor fibers supplying the third portion of the subclavian artery.

Before proceeding with an enumeration of the symptoms produced by the factors re-

TABLE I.—INCIDENCE ACCORDING TO AGE 142 PATIENTS WITH SYMPTOMS OF CERVICAL RIB OR THE SCALENUS ANTICUS SYNDROME

sponsible for the scalenus anticus syndrome, I should like to present a word of caution and suggest that clinicians and surgeons consider other causes for pain in the shoulders, arms, and neck. I agree with Ochsner and associates, Eaton and McGowan who have emphasized that numerous conditions may produce pains about the shoulders, neck, arms, and hands. The more common ones are bursitis, cervical arthritis, myositis, fibrositis, brachial neuritis, Raynaud's disease, thromboangitis, neoplasms within the spinal canal, neoplasms of the peripheral nerves and protruded intervertebral disks. In addition to all these, there are added the functional elements—exemplified by the patient who complains of pain here and there which includes the shoulders, neck, head and even the arms at some time or other. I presume that it is needless to emphasize the importance of a careful study and an accurate differential diagnosis. It is certain that scalenotomy will not relieve the symptoms which are produced by the lesions just mentioned.

SYMPTOMS

The symptoms vary according to the structure chiefly involved (45, 46, 50, 51, 53). Pain is the most common symptom. Often a pulsating mass can be detected above the clavicle; a bruit may be elicited in the same area. Paresthesia and anesthesia are not uncommon. Paralysis occurs less frequently, as does gangrene of the finger tips. Symptoms of vaso-

motor disturbances appear rather frequently. One hand is cooler, more sweaty and dusky, although not truly cyanotic, than the other hand when the condition is unilateral (22, 35).

Onset of symptoms. Cervical ribs have been recognized in children (41) by the presence of a tumor in the neck. Murphy and Donaldson thought the most common age of the patient was from 12 to 18 years. Beck thought the symptoms were first manifested after the patient had reached the age of 30 years. Evans believed they appeared between the ages of 20 and 30 years. The youngest patient in the present Mayo Clinic series was 14 years old and the oldest was 63 years (Table I).

The pain may be sharp and lancinating or a dull ache. It usually courses downward over the ulnar and median nerves, but occasionally extends upward to the shoulder and into the neck. The pain may be more or less continuous but invariably it is exaggerated by rotation of the patient's head or a forceful downward pull of the shoulder. If patients have been told that they have cervical ribs, they are likely to complain of vague pains and general discomfort about the neck and shoulders which I doubt can be attributed to the existence of short cervical ribs. The patient with cervical ribs that actually produce symptoms usually gives the history of pain which follows any sudden or violent exertion. Housewives usually complain of extending pain after sweeping, washing or dusting. One woman complained of pain and numbness along the distribution of the ulnar nerve after difficult labor. A physician complained of severe pain that extended along the median and ulnar nerves after he had struggled with an insane patient who attempted to commit suicide. Hyperesthesia, paresthesia and anesthesia may be associated with the pains and may persist after strenuous exertion. Atrophy of the muscles supplied by the brachial plexus occurs infrequently when it does occur it is manifested late in the course of the disease and is rarely complete.

Vascular symptoms may be ranged in three categories. The first are those which result from changes in blood flow, the blood flow being altered by varying degrees of constriction of the subclavian artery. Patients will com-

Fig. 6 The operative incision and the anatomic structures in the posterior triangle of the neck.

plain of not being able to work with their hands raised above their shoulders or of not being able to drive a car, to lift a heavy object or to sleep on their sides because one or more fingers become numb when they attempt such things.

The second group of vascular symptoms are caused by actual organic changes (22-35) in the subclavian artery and its terminal branches, characterized by occlusion of the radial, ulnar and brachial arteries and the appearance of edema, cyanosis and gangrene of one or more fingers.

The third group of vascular symptoms are caused by disturbances of the sympathetic nervous system (43) characterized by vasomotor changes not unlike those observed in Raynaud's disease (39). The skin covering the hand is more likely to remain cool, dusky and moist rather than to pass through color changes such as occur in Raynaud's disease. Horner's syndrome on the affected side has been observed many times.

The scalenus anticus syndrome without the presence of a cervical rib has been established as an independent entity. Naffziger and Grant Ochsner, Gage and DeBaKey, Jelasma, Love and others have ably described the syndrome and have supported their opinions by reports of cases. The only additional comment I can make is to emphasize the importance of an accurate diagnosis if relief is to be expected from scalenotomy.

SURGICAL TREATMENT

A collar incision (1-3) is made for a distance of about 5 centimeters, extending upward and backward from the sternoclavicular articulation over the posterior triangle. The dissection is carried through the platysma myoides muscle and fat until the tendon of the sternocleidomastoid muscle with its attachment to the clavicle is exposed. The clavicular attachment is divided between two forceps. The muscle portion is then reflected mesially so that the tendon of the omohyoid is exposed. This tendon is divided and the tendinous attachment of the scalenus anticus muscle, with the phrenic nerve running obliquely across it from the lateral to the mesial border is exposed (Fig. 6). During dissection the transverse cervical and the suprascapular arteries are divided and ligated. The scalenus anticus muscle is dissected free and the phrenic nerve is retracted mesially before the tendinous and muscular insertion is divided. The subclavian artery will appear on the lateral side of the scalenus anticus muscle and if the space between the cervical rib (or the cervical rib and the tendinous bands to the thoracic rib) and the lateral border of the scalenus anticus muscle is narrow the surgeon immediately observes compression of the subclavian artery against the trunks of the brachial plexus. On the mesial side of the scalenus anticus muscle the pleura may be observed and if dissection is carried still farther mesially the carotid sheath and the vertebral

Fig. 7. Steps in the surgical procedure and in protection of the subclavian artery during operation: a, insertion of strip of cotton bet. cen. the subclavian artery and the scalenus anticus muscle; b, use of electrocoagulation to control bleeding while the tendinous muscular attachment of the scalenus anticus muscle is being sectioned; c, sectioning of the musculotendinous insertion of the scalenus anticus muscle with scissors; d, when the scalenus anticus muscle has been sectioned, the subclavian artery slides forward and assumes normal caliber and the lower trunk of the brachial plexus likewise slides forward and downward.

artery will be exposed this, however is unnecessary.

It is important to carry the dissection upward on the anterior surface of the scalenus anticus muscle for a distance of 5 centimeters in order to expose the phrenic nerve thoroughly before it is retracted medially. The surgeon must bear in mind before he divides the scalenus anticus muscle at its insertion that it lies over the compressed portion of the subclavian artery and that the pleura is situated medially to the inner border of the muscle in order to avoid injury to both structures. Sectioning of the musculotendinous insertion is most easily accomplished by sectioning the fibers in small groups with scissors (Fig. 7). The cut fibers promptly retract upward, thus exposing the undivided fibers and the compression of the artery. As soon as the scalenus

anticus muscle has been divided, the subclavian artery will be seen to slide downward and take on its normal caliber and the lower trunk of the brachial plexus likewise will slide forward and downward. In the event that there are adhesions between the artery and the brachial plexus, gentle dissection will be necessary to liberate both. Care is required to avoid injury to the vasa vasorum for if they are injured extravasation of blood will take place between the muscular and adventitious coats of the subclavian artery.

Before the surgeon proceeds with sectioning of the bundles of muscle fibers of the scalenus muscle, it is advisable to separate the muscle from the subclavian artery and protect it during the operation by slipping a strip of cotton between the two. This will permit the surgeon to use the electrocoagulating current to control the bleeding while he is sectioning the tendinous muscular attachment of the scalenus anticus muscle. If the muscle is hypertrophied and bulky it is advisable to resect 3 to 5 centimeters off the lower free end. The incision should be made diagonally across the muscle to avoid a postoperative lump in the neck.

Craig and his assistant in 1937 emphasized the necessity of resection of a portion of the cervical rib in addition to performance of scalenotomy (15-17). Partial removal of the cervical rib is indicated when the rib is completely formed and occupies a high position as it turns downward (Fig. 8a and b) compelling the lower trunk of the brachial plexus to ride up over it before it continues its course. I remove this portion with a rongeur exposing the amount I wish to remove by retracting gently the lower trunk of the plexus downward and the middle trunk upward (Fig. 9). If it is necessary to operate on both sides, I do not hesitate to do so during the same operation, and I have not found any contraindications to such a procedure.

Before closing the wound I reflect a flap of fat between the brachial plexus and the subclavian artery to minimize adhesions and scarring. The wound is closed in much the same manner as any operative wound is closed. The scalenus muscle retracts upward. If division of the omohyoid tendon has been necessary it

usually is reunited by suture before the clavicular portion of the sternocleidomastoid muscle is resutured with mattress sutures of chromic catgut. The patient may be permitted to sit up on the day after operation. He may be dismissed from the hospital after 3 days and from the surgeon's care as soon as the wound in the skin has healed.

When the technique of the anterior approach and division of the scalenus anticus muscle is compared with the former lateral approach and resection of a cervical rib, the advantages of the anterior approach are readily appreciated, to say nothing of the relative effectiveness of the procedure. The anterior approach can be carried out with ease and without danger of traumatizing the brachial plexus, whereas the latter requires considerable dissection and retraction of the brachial plexus.

REVIEW OF SCALENOTOMY 1925 TO 1946

The review includes the patients for whom scalenotomy has been performed at the Mayo Clinic during a period of 22 years from January 1925 to December 1946 by members of the neurosurgical staff. There are 142 patients in the series. They have been divided into three groups A, B and C for comparison of the incidence according to sex and age, marital status, sides involved, occupations, groups of symptoms and results (Tables I, II, III, IV and V). In group B, some members of which underwent combined operations of scalenot-

omy and resection of cervical ribs, 9 patients were operated on during 1925 and 1926 when I was convincing myself that scalenotomy could be substituted for resection of cervical ribs in most of the cases. Thus there remain 17 patients for whom since 1927 it was believed that the combined operation was indicated.

Group A includes patients for whom scalenotomy was performed without resection of cervical ribs (63 patients). Group B includes patients for whom combined operations were performed, that is, scalenotomy and resection of cervical ribs by the anterior approach (26 patients). Group C includes patients for

Fig. 9. The anterior approach to the cervical rib when resection is advisable.

whom scalenotomy was performed in the absence of cervical ribs (53 patients)

It is rather difficult to give a comprehensive picture of the symptoms of the scalenus anticus syndrome whether it be associated with the presence or the absence of cervical ribs, since in one case the paresthesias and vascular phenomena may be more prominent whereas in another case the pain which is exaggerated by certain movements may be the only symptom present.

Pain in one form or another is the most common symptom followed in order of frequency of occurrence by paresthesias, vascular disturbances and motor or sensory loss. Unilateral vasomotor changes occurred in more than a third of the patients. In 7 patients the vasomotor changes had to be distinguished from those which characterize Raynaud's disease. Two patients had undergone amputation of the index finger. Four presented gangrene in the first and second fingers of one

hand. The radial pulse was absent in 11 patients.

In group C in which cervical ribs were absent the transverse process of the seventh cervical vertebra was unusually large in 16 cases. In the same group the scalenus anticus muscle appeared to be more hypertrophied and more often contained fibrotic bands than was true in those cases in which cervical ribs were present.

division of the subclavian artery could be effected the other recovered without complications. Many patients had a fusiform enlargement of the subclavian artery in its third portion lateral to the scalenus anticus muscle but only one patient had an aneurysm (28 30 38). Our patients had anomalous high arched first thoracic ribs.

The surgical results were both satisfactory and disappointing (Table V). In groups A and B approximately 54 per cent of the patients were relieved of all their symptoms. Approximately a third were greatly improved. They were able to return to their vocations and to carry on but were annoyed by twinges of pain during certain movements. These recurrent symptoms were in all probability caused by adhesions in the surgical wound (21). Results of secondary surgical exploration verified this opinion. One patient did not obtain relief by scalenotomy but secured complete relief after a secondary operation in which the omohyoid muscle was divided and flaps of living fat were used to cover the trunks of the brachial plexus. In 4 other patients the omohyoid muscle was divided at the time scalenotomy was performed. For 5 patients unilateral cervicothoracic sympathectomy was performed in conjunction with scalenotomy. For 4 patients thyroidectomy was performed at the same time that the scalenotomy was done.

In review of the table concerned with results (Table V) it is apparent that the results in group C which includes those patients for whom scalenotomy was performed in the absence of a cervical rib were not so satisfactory as the results obtained in groups A and B. Slightly more than a third of the patients in group C were relieved of their symptoms many were improved by surgical treatment whereas for others the treatment accomplished little or nothing. The reason for this, I believe is too liberal selection of patients for surgical treatment and disregard for the vascular test. Too often the neurosurgeon has been prevailed on to do something when other measures have failed. Perhaps the physician interested in psychosomatic therapy should be called more often in consultation in this particular group of patients. The surgical results

bear a direct relationship to the pathologic anatomy.

CONCLUSIONS

Scalenotomy and sectioning of the insertion of the scalenus anticus muscle, occasionally with resection of the distal portion of the muscle when the muscle is markedly hypertrophied appear to constitute the operation of choice for the condition under consideration.

A combined operation meaning scalenotomy and resection of cervical ribs is indicated when the cervical rib is completely formed and is situated high in the neck so that the brachial plexus must ride over the rib in its course into the axilla. Subtotal resection of the cervical rib can be accomplished with the use of a rongeur through the same wound by separation of the middle and lower trunks of the brachial plexus.

RESECTION OF THE KNEE JOINT FOR SUPPURATIVE ARTHRITIS

JAMES E. THOMPSON M.D., F.A.C.S. CHARLES F. STEWART M.D. and
WILLIAM H. CASSEBAUM M.D., F.A.C.S., New York, New York

SUPPURATIVE arthritis of the knee joint is a serious disease. Rarely is the joint restored to normal. If the condition persists any length of time destruction of cartilage and bone is such that a painful knee results. In many cases amputation is required to combat the sepsis which not infrequently results in death. It is not a common condition in civil practice but is a hazard present in all penetrating injuries of the knee.

During the early period in which the 9th Evacuation Hospital acted as a general hospital for the French we encountered 6 patients with wounds of the knee which were either suppurating at the time of arrival or developed suppuration soon after. Characteristic destructive changes occurred in the cartilage of the joint. In 2 of the earliest cases the knees were drained widely by 4 incisions. These incisions were made early in the course of the infection but the destructive changes occurred despite their use. This result corresponded with our civilian experience that is that in a case of suppuration of the knee no matter what the treatment the result is a permanently damaged joint.

At about this time we heard of the practice of resection of knee joints in the presence of infection a procedure the French surgeons had been using for years and one they attributed to Ollier. Naturally our first reaction to the idea of resection earned out during the course of sepsis was one of violent opposition. It seemed like a very radical procedure to cut through infected soft tissues bone and cartilage to disturb the area of resistance seemed to violate a surgical principle. On the other hand the French advocates of this procedure pointed out its advantages. Major Curtillet the consulting surgeon to the French forces influenced us to try it. As he presented it the

procedure was not new but had been tried prior to the first World War by the French.

In brief the resection consists of removing the femoral condyles at the highest level attained by cartilage and the upper half inch of the tibia. The synovia is then excised. The object of the operation is to shorten the course of sepsis by removing feebly resistant cartilage and the areas of infected bone and synovia. Once these become involved they remain so for a long time. Life and limb are saved by diminishing this period of sepsis, during which the patient becomes very toxic and depleted. The procedure accepts the fact that suppurative arthritis in the knee results in a permanently damaged joint which is either ankylosed or possesses some degree of painful motion. Consequently the fusion is performed at the earliest possible moment thus saving the patient time and suffering. The operation removes the suppurating tissues of low vitality which harbor infection and at the same time secures really adequate drainage. Success is not always achieved. Major Curtillet was frank to say that occasionally nothing is gained and that amputation is not avoided. He did not fear untoward effects from resecting suppurating joints. The optimum time to resect is early in the first 2 weeks.

Resection of a joint in the presence of infection is often referred to by the French as secondary resection. The term primary resection is used for resection done at the time of débridement and is done because the operator feels that destruction of articular surfaces precludes the return of good function to the joint and that joint infection will develop. French surgeons do primary resections of practically all joints even phalanges though we have seen it used mostly for knees and elbows. We have since resected a few joints ourselves when the indications were very definite.

From the Surgical Service, R. Meade Hospital, New York.

Fig. 1. Case 2. a March 4—1 month after bounding, healing, external tibial fracture and destruction of cartilage of femoral condyle. Detail is obscured by plaster. b

Three months after resection. A little callus is present anteriorly. Only the slightest amount of motion could be produced by manipulation.

namely when fractures were so extensive that there was no hope of regaining any joint function.

OPERATIVE TECHNIQUE FOR RESECTION OF THE KNEE JOINT

A variety of incisions are used. The transverse incision employed by Major Curtillet seems best. This is an elliptical transverse incision removing the patella. The anterior and posterior cruciate ligaments are divided and the knee joint is flexed—an assistant supporting it with a rolled bath towel in the bend.

The femoral condyle is sawed off at a level just proximal to the intercondylar fossa, and the remaining cartilage stripped free from the underlying bone. The tibial condyles are then sawed off as conservatively as possible but removing all joint surface. Cuts are made so that 5 to 10 degrees of knee joint flexion result. The synovia is completely excised. If a tourniquet has been used it is now removed. Drains are placed at the angles of the incision. One heavy wire suture may be placed through the anterior margins of the bones to prevent forward or backward slipping. A few

Fig. 2. Case 3. a and b Roentgenograms taken February 7, 1944. Circular defect made in posterior part of medial condyle at first operation can be seen on lateral view.

There is no detectable erosion of weight bearing surfaces. c and d. Show marked erosion of condyles seen on March 12, 1944, the day before operation.

sutures may be inserted to approximate skin loosely and to prevent retraction. Dressings and a spica are applied. Drains are removed in 5 to 10 days and the spica is changed as needed. It does not take long for muscle shortening to close the gap. In cases in which the wound is on the posterior aspect of the knee the wound may be enlarged and used for dependent drainage. Otherwise one turns the patient, in the spica face down at intervals. As frequently there remain fractures of the bone adjacent to the resected joint abscesses which require drainage may develop.

It is not our purpose in this paper to discuss the clinical features and course of this disease, but one pathological feature is worthy of note. The earliest destruction of cartilage occurs at the points of contact between the two bones. The greatest damage is found at these points as the lesions advance. The medial femoral condyle is usually first involved. This observation has been previously described by Phemister and others.

Another point which experience and previous observations have tended to confirm is the inadequacy of any prescribed means of draining the knee. We have used 2 large parapatellar incisions together with a third one behind the medial ligament and a fourth just posterior to the lateral ligament. Two of the cases about to be described had drainage of

this sort. These incisions may relieve the tension of the pus, but pools remain in the deep recesses of the joint, and a film is retained between surfaces in close contact. Here between the condyles and between the menisci and condyles the film of pus is held by capillary attraction.

CASE REPORTS

Following are 6 case reports which form the basis for this paper.

Fig. 4 Case 3. Roentgenograms taken 6 weeks after operation. Note the evidence of callus formation.

b. June 6, 1944, 3 months, minus 1 week, after resection. Fracture line still visible but with callus seen in angulus. Knee solid on x-ray.

CASE 1. This patient, a Tunisian Arab, was wounded by a bullet on January 27, 1944, at 8:00 a.m. The missile entered the left knee medially and made its exit through the posterior aspect of the upper third of the calf. After 24 hours' first aid treatment was given including local sulfanilamid powder. About 64 hours after injury the patient was operated upon in a mobile French hospital. At operation it was found that the knee joint had been opened and that there was a complete fracture of the medial tibial condyle. The knee joint was not closed; the wound was dressed and the leg placed in a cast.

Ten days after injury the patient arrived. He appeared acutely ill, pale but his temperature was normal. He complained bitterly of pain in his knee and because of this on the following day the cast was removed and the wound was redressed. Because of diffuse swelling in the knee region and extreme pain on motion purpurative arthritis was suspected. The wound was dressed and a cast was reapplied. The patient's temperature rose thereafter and ranged between 101.8 and 104.8 degrees. On his 4th day in our hospital the knee joint was aspirated and cultured (*Bacillus hemolyticus* (streptococcus) infection) incision was made into the knee joint at four places and three Penrose drains were placed in the joint. Day to day repeated transfusion and parenteral sulfonamide therapy the patient continued to run a septic temperature curve. This septic course continued; the patient lost his appetite, suffered occasional chills and looked extremely ill. Finally 23 days after admission and 20 days after drainage of the knee joint amputation was decided upon as the only procedure which would save the patient's life. Resection of the joint was considered but abandoned as the patient had no experience with it. A guillotine amputation through the lower third of the left thigh was done. The amputated knee revealed extensive periarticular edema. Covering the entire edematous synovial lining of the joint was a

hemorrhagic fibrinous exudate. There was destruction of the cartilage on the weight-bearing surfaces of the femur and tibia down to the bone. Progress following amputation was satisfactory.

CASE 2. This young adult Arab was wounded on February 3, 1944, by a bullet which perforated the upper tibia from behind forward. The fracture was badly comminuted and was of the inverted V type with the fracture lines extending into the joint. Excision of the wound of exit and wound toilet were performed at a French evacuation hospital about 24 hours after injury.

On his arrival on February 12, 1944, the patient seemed quite ill and had a fever of 103 degrees. Next day the cast was removed revealing a wound 3 by 2 centimeters about 5 centimeters below the patella and another wound 1 centimeter in diameter in the popliteal space. The anterior wound which was discharging foul blood tinged pus was enlarged. Sulfanilamid powder was instilled and a plaster applied. X-ray film revealed the fracture described and several small foreign bodies about the fracture site. A blood count on February 18 revealed a hemoglobin of 54 per cent, Sahli red blood cell 2,900,000, white blood cell 34,000 with 75 per cent polymorphonuclears. After the drainage procedure the fever dropped to 100 degrees and remained so for only a few days.

During the succeeding 3 weeks the patient ran a septic course and went progressively downhill. He had surprisingly little pain. In this period he received intravenous plasma, blood, and sulfadiazine therapy. On March 4 x-ray films showed osteomyelitis of the tibial condyle, narrowing of the joint space and evidence of destruction of condylar cartilage—the picture of acute suppurative arthritis. Serum protein was 5.6 milligrams per cent, hemoglobin 60 per cent, red blood cell 3,950,000, white blood cell 20,000 polymorphonuclears 80 per cent.

On March 11—3 weeks after injury—there was foul smelling pus exuding from both a tibia and posterior wound. The knee joint was distended

Resection of the knee joint was decided upon and done that day. A U^h incision base upward was used. The joint was filled with thick, gray pus. The femur was sawed across at the highest point reached by the articular cartilage. The tibial articular surface was resected with rongeurs and curette. It was impossible to do otherwise as the large condylar fragments were so free and we were anxious not to disturb the remaining bone and its blood supply. The edematous synovia was excised. Dressings and a spica were applied after placing drains laterally and medially. The leg was held so that an inch gap between the bones was maintained. No suturing of the skin or flap was done, but the patella was removed. Cultures made at the time of operation grew β hemolytic staphylococcus and a β hemolytic streptococcus. One thousand cubic centimeters of blood was given postoperatively.

Examination of the excised specimen showed a large area of destruction of the medial femoral condyle. The same type of lesion involved the lateral

condyle but to a lesser extent. On both sides bone was involved but only a few millimeters were necrotic. The cartilage of the contact surfaces of the tibia was also gone but destruction of the underlying cortex was minimal. The menisci though still present, were soft and the sharp inner edges dissolved. The periarticular tissues were slightly swollen.

Liberation of pus is thought to account for the abrupt fall in temperature which resulted. The patient's immediate postoperative course was very satisfactory with the temperature remaining near normal. Two and a half weeks after resection the patient developed a spiking fever and a large abscess communicating with the fracture and extending down the lateral anterior fascial compartment of the leg was drained. Culture of this abscess showed that *Bacillus pyocyaneus* had been added to the organisms originally present.

Improvement following this drainage was short lived and 10 days later on April 8 a pooling of puru-

lent drainage noted between the end of the femur and tibia was drained posteriorly. During this procedure an old hematoma anterior to the tendon of the semimembranosus muscle was found and evacuated. At the same time moderately deep jaundice was noted as well as splenic enlargement. The jaundice was felt to be due to a nonhemolytic transfusion reaction. During this period (March 29 to April 15) penicillin became available and was given. The temperature remained normal after the second drainage and remained so until the patient was evacuated May 31. At that time he could raise the limb off the bed without pain. When the knee site was tested for motion a minimal amount could be produced and this was painful. All wounds were healed except a small granulating area 1 by 1.5 by 2 centimeters deep between the tibial condyles. The knee site was kept immobilized to promote union. His general condition was excellent. Roentgenograms on May 31 showed the bones in perfect apposition and the leg straight. There was a little callus visible at the anterior edge of the tibia. Between the condyles of the tibia was an area of decreased calcification. No evidence of sequestra was present.

This was the first case in which resection was performed. Resection should have been done much earlier. The complicating abscesses were due to osteomyelitis of the fractured tibia. It was this in fact which had led to suppuration of the knee, as the missile had not passed through the knee joint. The immediate response to resection was excellent. Adequate drainage was obtained. Although the course

of the infection was long it would have been longer—and the toxemia greater—had the knee not been resected. Life and limb were being threatened. Bony union had not been obtained at the time of evacuation (4 months after injury, and about 3 months after resection). It is believed a satisfactory union bony or fibrous, will result. Residual infection in the tibial condyles and our failure to place the bones in apposition soon enough, and general debility are the possible causes for the failure to secure early fusion. The extensive comminuted fracture was a bad set up for any treatment.

CASE 3. This white French soldier received a shell fragment wound in the outer aspect of the right knee on February 2, 1944, at 10:30 a.m. At 8:00 a.m. on February 3, 1944, he was operated upon at a French evacuation hospital. The shell fragment was removed from the posterior part of the lateral femoral condyle through a posterior incision in the popliteal space. This approach traversed the joint. The entrance wound was incised but not divided.

Four days after wounding he was admitted to hospital complaining of pain in the knee and with a fever of 100 degrees. He gave a history of chronic malaria recently treated.

Incision of the wound showed a long, clean, granulating vertical incision. The wound of entrance was now 1½ inches long and situated just above and anterior to the head of the fibula. Pressure on the suprapatellar pouch caused clear synovial fluid

to exude. During the subsequent few days this fluid became purulent as his temperature rose to 102 degrees.

On February 11 the knee joint was drained under pentothal anesthesia. Two anterior incisions were made as well as posterior ones. These latter drained the posterior portions of the joint behind the condyles. Penrose tubing was inserted. It was interesting to note that relatively clear joint fluid was obtained through the posterior incisions while frank pus was present in the suprapatellar pouch. A smear of this showed staphylococcus.

During the following month the patient's course continued septic. Temperature peaks varied between 101 and 102 degrees. The resulting anemia (red blood cells 2,800,000 and hemoglobin 61 per cent) was combated successfully with six blood transfusions (blood count on March 12: red blood cells 4,600,000 hemoglobin 78 per cent white blood cells 11,500). Sulfadiazine irrigations and immobilization in a spica did not prevent destructive changes in the joint as shown by x ray on February 26. Roentgenogram revealed narrowing and early necrosis of the bone of the medial and lateral condyles. After consultation with Major Curtlett of the French Army a resection was done on March 13.

Under general anesthesia and with a tourniquet in place the lower ends of the two lateral drainage incisions were extended distally and curved to meet thus forming a U. This incision included all layers. The patella was excised. After the cruciate ligaments were severed the knee joint was flexed and the femur dislocated anteriorly into the wound. About 13 1/4 inches of the femoral condyles were removed with a saw, the joint surface being removed. Approximately a half inch of the tibial condyles was then sawed off. Following this all the remaining synovia was excised. The U flap was sutured with two wire sutures, wide open drainage sites being left laterally. No drains were inserted. The raw bony surfaces of the femur and tibia were placed in contact in 5 degree flexion and a spica was applied.

A culture of the pus obtained at operation showed *S. pyocyanus* and a diphtheroid bacillus. The joint had contained pockets of white, thick pus, and all the contact surfaces of the femoral and tibial condyles were eroded. The menisci were completely dissolved and the cruciate ligaments had almost disappeared. The synovia was edematous and hemorrhagic.

During the first month after operation his temperature course continued to suggest sepsis. His spica was twice changed and the local area found to be doing well. Finally on April 9 after a temperature rise to 104.2 degrees, accompanied by tenderness over the liver a positive smear for malaria (*Plasmodium vivax*) was obtained. Malaria had long been suspected but previous smears were negative and no therapy was given until this time.

Under stabine therapy his temperature returned to normal. On April 18 an x ray film showed callus developing (5 weeks after operation). Clinically the

knee fusion was firm under gentle manipulation. Two weeks later the spica was discarded and a cast was applied. The patient was soon up and around walking with crutches. On June 1 he was evacuated to Africa.

A letter from him in August of the same year stated his wounds were well healed and that he was bearing weight though still using crutches.

This case represented a very severe staphylococcus suppurative arthritis of the knee complicated by recrudescence of an old chronic malaria. His marked sepsis produced a profound secondary anemia that required many transfusions. In the light of more recent experience arthrotomy with thorough cleansing of the joint irrigations and local penicillin instillations (which was not then available) might have cleared up the impending suppuration if it had been performed during the first few days after admission. His progressively downhill course makes us believe that it would have been necessary to amputate his leg in order to save life, if the arthrectomy had not been performed. His primary treatment can be criticized for its failure to close the deep layers of the wound of entrance, and in applying a mid thigh cast instead of a spica.

CASE 4. This 32 year old Tunisian Arab was wounded at 11:00 a. m. February 2, 1944, by shell fragments. Forty-eight hours later he was operated upon at a French evacuation hospital and the following is a summary of their note.

Left leg. Compound fracture of the lower tibia. The wound was excised, and 2 other large wounds of the same leg were debrided radically. A comminuted fracture of the medial femoral condyle with an opening into the knee joint was treated by excision of the entrance wound and establishment of through and through drainage of the suprapatellar pouch half inch rubber tubing was used. The leg was immobilized in plaster to the hip. In addition large wounds of the right calf and left hand were present.

The patient was received by us on February 6, 1944. His temperature was 101 degrees, pulse rapid and he was stoically bearing considerable pain. The wounds were inspected the next day and this note was made: Has an open wound of the left knee with projecting heavy rubber tubes. These removed. Some gray yellow slough, where there has been contact between the wound edges and the rubber tube drains. It would be impossible to close the joint. There is no swelling of the knee. [Other wounds then described.] All wounds clean. Sulfanilamide vaseline gauze and a cast applied to left knee. Culture of the tracts into the knee joint later grew *Staphylococcus albus* and a diphtheroid bacillus.

The patient was given supportive treatment consisting of plasma, transfusions sulfadiazine, vitamins and iron.

During the next 12 days the patient's pain diminished somewhat but fever with daily rises to 102 or 103 degrees persisted. On February 13 his hemoglobin was 54 per cent, red blood cells, 2,500,000, white blood cells, 10,250 with 76 per cent polymorphonuclears. February 19 the patient was re-dressed. There was little tenderness, and no destruction of the joint, but pressure on it caused a slight synovial leak. It was felt that the fever was due to his other wounds especially the compound fracture which presented a small pool of brownish pus.

On March 10 the cast was again removed and at this time any movement of the knee was painful. There was some periarticular swelling but no increase in joint fluid. An x-ray film showed evidence of marked bone destruction involving practically all the articular surfaces of the knee (Fig. 5). Destruction is particularly marked in the region of the medial femoral condyle. Fever to 102 degrees daily persisted.

On March 15 the knee joint was resected. During preparation of the leg, flexion caused the now closed medial drainage wound to pop open and discharge some granulation tissue. No other fluid was present in the joint. Destruction of cartilage and bone was noted on the contact surface of the medial femoral condyle. The medial tibial condyle showed less marked destruction. Some of the medial meniscus had been digested. The synovia was gelatinous. The lateral condyles of femur and tibia were eroded of cartilage where there had been contact. Cultures made from the joint fluid grew a weakly hemolytic *Staphylococcus aureus*. The operation was performed by Major Curtlett, French consultant surgeon, who resected an inch of femoral condyle and the articular surface of the tibia. A single wire suture was placed in the bone ends to prevent the surfaces losing contact and sliding back and forth. Rubber tube drains were placed at the lateral and medial ends of the transverse incision through which the patella had been removed. The wound edges made contact without suture. The knee was flexed 15 degrees. A spica was applied.

Before operation the patient had received 6 transfusions of 500 to 600 cubic centimeters each. The last two were accompanied by rather severe reactions. The preoperative blood count was hemoglobin, 64 per cent, red blood cells, 3,200,000, white blood cells 5,900, with 63 per cent polymorphonuclears.

The temperature course during the next 17 days was not changed by the resection. During this period the spica was twice changed. The drains were removed on March 25—10 days postoperation. Cultures at this time showed that the *Bacillus pyocyaneus* as well as the *staphylococcus* was now present in the wound.

When we obtained some penicillin the patient was given 1,270,000 units during a 6 day period (March

28 to April 3). In the subsequent 2 to 3 weeks his temperature gradually fell to normal. His last count on April 15 was hemoglobin 71 per cent, red blood cells 3,580,000, white blood cells 7,400, with 52 per cent polymorphonuclears.

The patient's wounds were skin grafted on May 4, and he was finally evacuated to Africa June 18—1 month after being wounded. The knee was solid and weight had been borne in spite of a nonunion of the fracture of the lower third of the tibia. The fracture line between the condyles was easily visible by x-ray and there was little callus. No one would not have hesitated to allow weight bearing had it not been for the leg fracture.

A letter written by him on August 3, 1944 from Africa stated that union of his leg fracture had not yet occurred.

As far as the knee is concerned, this patient's convalescence was shortened by resection. With the amount of joint destruction which occurred any motion would have been painful and there would have been deformity as well.

In retrospect we believe thorough débridement—even 48 hours after wounding—with closure of the joint, might have prevented infection. Under the newer program to be described later we too could have closed the joint and prevented suppuration. In our opinion a joint left open for whatever reason should never be dressed until it becomes sealed by granulations, otherwise infection will develop. Contamination occurs during dressings no matter how carefully they are done.

CASE 5. This Arab received a perforating shell fragment wound of the right knee on March 3, 1944. The patella was comminuted. The shattered patella was removed and the popliteal space debrided at a French evacuation hospital.

He arrived at our hospital on March 7, 1944, in good condition in a hip spica. An x-ray examination revealed the absence of the patella and slight erosions of the anterior surface of the external femoral condyle. On March 11 because of pain and a slight fever his knee was inspected. At the lower end of a U-shaped Ollier incision a small portion of the femoral condyle could be seen. The wound edges appeared healthy and with a little undercutting the joint was closed without tension, fine wire sutures being used. The vertical popliteal wound was partially closed.

The joint infection became more apparent. Patient's temperature rose to 102 degrees. He developed an anemia and his blood count was, red blood cells, 3,010,000, hemoglobin 61 per cent, white blood cells, 10,400, with 77 per cent polymorphonuclears. Culture of the pus from both anterior and posterior incisions revealed *Staphylococcus hem-*

Fig. 10. Chart showing highest daily temperatures in Cases 2 to 6

lyticus and *Bacillus pyocyaneus*. A roentgenogram showed joint narrowing and further erosion of the external femoral condyle.

On March 17 an arthrectomy was done, with removal of 1 inch of the femoral condyles and $\frac{1}{4}$ inch of the tibial condyles. The synovia was completely excised. A small area of the medial femoral condyle had been eroded down into the cancellous bone. The joint contained considerable pus. Following removal of the condyles, two wire sutures were placed through the anterior edges of the cortex of both bones to hold them in proper approximation. Drains

were placed at the lateral angles. A hip spica was applied.

The patient's postoperative progress was very satisfactory and by May 4 (7 weeks) callus between the fragments was seen by x ray. His temperature had not risen above 99 degrees. One complication, a foot drop, developed postoperatively and was still present at the time of his evacuation to North Africa on June 1.

Arthrectomy was performed very early after the first evidence that suppuration and

If less bone is removed it is obvious no skin should be excised.

Resection of joints during suppuration has, we believe a place in American surgery. It is to be hoped that better surgery and penicillin will make its place a small one. Prevention according to a plan first advocated by Colonels Hampton and Lyons, made such strides that the number of suppurating joints markedly decreased. We subsequently performed arthrotomies on 202 penetrating wounds of the knee joint and although our follow up is limited we are reasonably sure that few have developed suppuration. The necessity of sometimes evacuating large numbers of patients did not permit us to be certain of a few of them who were evacuated within several weeks of injury. Many of the group were undoubtedly saved from developing knee joint infection by application of the plan here outlined.

The plan emphasized arthrotomies through adequate incisions of the joint whenever the presence of infection or devitalized tissue in the joint is suspected. A thorough débridement is then done with removal of foreign bodies, blood clot, and devitalized bone and cartilage. The joint is irrigated and the synovia is closed. Before closure 10,000 units of penicillin is placed in the joint. Irrigation with saline through a large needle and injection of penicillin are repeated if indicated. A spica must be used for adequate immobilization. Blood volume is restored by multiple transfusions.

The penicillin program as outlined will undoubtedly reduce to a minimum knee joint suppuration and we believe it should be car-

ried out before resection. We also believe that drainage may be attempted before decision is made to resect. If despite drainage the suppuration persists and destructive changes become visible by x ray resection should be recommended. This program may bring resection into the picture later than the optimum time for it and later than the French recommend. However the present results obtained by the combination of good surgery, closure of the synovia, penicillin and blood restoration seem to justify the delay.

SUMMARY AND CONCLUSIONS

- 1 Six cases of knee joint suppuration following shell fragment wounds are reported.
- 2 In 1 case amputation was done and the joints were resected in the remaining 5.
- 3 The resections were done during an active stage of suppuration.
- 4 No patient had any immediate reaction to the resection which was unfavorable. In 2 who needed drainage (Cases 2-6) the reactions were immediately favorable.
- 5 It is believed that the course of the infection has been shortened and that the resulting fusion of the knee is an acceptable end result.
- 6 It is believed this procedure properly carried out will frequently save life and limb by shortening a suppurative infection which not infrequently threatens both.
- 7 It is believed that a program of wide arthrotomy and thorough débridement with closure of the joint when possible together with penicillin therapy, transfusions as indicated and adequate immobilization will prevent knee joint suppuration in war wounds.

BREAST CANCER

HERBERT C. CHASE, M.D., F.A.C.S., New York, New York

BREAST cancer is the most common type of neoplasm having almost twice the incidence of that of the next site the cervix (Fig 1). Thirty seven of every 1,000 women who reach maturity will become victims of this disease and more than 15,000 women die annually from it in the United States (Fig 2). Moreover carcinoma of the breast is increasing at the rate of nearly 1 per cent per annum and is not a preventable disease. Cancer of the lip, the tongue, the skin and the cervix are lesions which in a measure may be prevented but so little is known of the etiology of breast cancer that little hope can be entertained at present as to its prophylaxis.

Yet, the present outlook in breast carcinoma is by no means discouraging. The facts and figures are all to the contrary and show that the prognosis is increasingly hopeful and constantly improving (Table I and Fig 3). Of the 15,000 women who die annually, 10,000 can be saved by surgery alone if the lesion is discovered while confined to the breast (Fig 4). (This means a salvage of 29 of the 37.) After the disease has spread to the axilla only 6,000 can be saved by surgery, x-ray and radium combined (Fig 5). Our greatest hope for continued progress in the problem of breast cancer lies in a program of education of both patient and practitioner toward early diagnosis and in the education of surgeons toward a more thorough, extensive and meticulous radical operation.

to examine their breasts monthly during the mid period. This will place a good part of the responsibility where it will best be met—on the patient herself. She will educate others. This instruction is not so likely to produce unfounded fears as it is to lead to the satisfaction which comes from early discovery of any lesion which may arise.

A slow but steady improvement is being made in the radical breast operation. Surgeons, realizing that standardization is often a barrier to progress, are getting away from the old limited orthodox types of procedure such as the Halsted and Willy Meyer. With a broader concept based on the more recent elucidation of the pathology, the modes of spread, the routes and pathways of spread and with an intimate knowledge of the anatomy, the radical dissection is being extended and we are operating not only with our eye but with our mind's eye.

Sampson Handley has made two definite additions to the radical breast operation: a wider area of fascial removal and removal of the epigastric nodes. For many years we have constantly emphasized: (a) the necessity of a systematized procedure to gain thoroughness; (b) the necessity of completely mobilizing skin flaps for better exposure and haemostasis; (c) the removal of all superficial fascia from the skin flaps; (d) a method to avoid handling or squeezing the breast during the operation; (e) a method to insure the removal of all five groups of nodes (including subscapular and

A more thorough technique a greater dissemination of proper technique and its more regular use by larger and larger groups are some of the basic reasons for gradual improvement in results. There has also been gradual improvement in x ray equipment higher voltage machines, improved methods (Coutard etc) and technique all of which has meant added success.

Early diagnosis continues to be of paramount importance this one factor counting for the salvage of 4,000 additional women each year. While it is not possible nor appropriate to go into the details here of the diagnosis and differential diagnosis of breast cancer certain vital facts should be repeatedly emphasized. (1) Seventy per cent of all breast lesions admitted to the hospital are malignant. (2) Peau d'orange elevation or retraction of the nipple axillary node involvement are the signs of advanced carcinoma of the breast and it is negligent to await their development. (3) A knowledge of three simple lesions fibrocystic disease, fibroadenoma and cysts will together with carcinoma, comprise the diagnosis in 87 per cent of cases. (4) The patient with fibrocystic disease is five times more likely to develop cancer than the corresponding age group with normal breasts (Fig 6). This is the only type of breast lesion in which 'observation' and repeated examination is indicated and safe. (5) Most important of all it should be

repeatedly emphasized that there is *not any kind* of discrete mass in the breast that does not require removal and microscopic examination. The policy should always be 'look and see, not 'wait and see.' If there is a discrete mass observation is neglect. Carcinoma often masquerades as mastitis and mastitis masquerades as carcinoma. This is particularly true in the diffuse papillary type of fibrocystic disease and in the menopausal woman with ectasia and periductal mastitis. (6) It should also be emphasized that the commonest of all breast lesions (fibrocystic disease) is the most difficult to differentiate when localized and the very one in which cancer is most likely to occur. These facts make frozen section imperative in this type. (7) Bloody discharge from the nipple means carcinoma until proved otherwise. About 50 per cent of papillary cyst adenomas and intraductal papillomas become malignant. (8) Skin dimpling, fixation, or tethering is one of the latest of the early signs and one of the earliest of the late signs. Do not depend on it nor wait for it. (9) Axillary nodes are not palpable in 30 per cent of cases when involved. Another 30 per cent will show only hyperplasia in breast malignancy. (10) In about 95 out of 100 times the diagnosis can be made in the 'gross' when the lesion is removed. In the five doubtful or borderline cases frozen section is a reliable procedure. Aspiration biopsy is of definite but limited value. A negative means nothing. It is of limited application because many lesions by their very nature require a tissue pattern for

Fig. 2. Fifteen thousand women die annually in the United States of breast cancer.

ing with these facts are the statistics of China. For centuries dating back to the Ming Dynasty (1368-1462 A.D.) Chinese women of the upper or Mandarin class have abhorred large breasts (and large feet). It has long been their custom to bind their breasts as soon as the baby is born and turn the infant over to an Amah (wet nurse). The statistics of China show that the incidence of carcinoma of the breast among the Mandarin women is the highest in the world and among the Amahs the lowest recorded. Castration produces no such involutional effect on the breast. In fact the anterior pituitary and adrenal cortex make up a compensatory mechanism for the manufacture and excretion of steroids to the end that after castration the estrogen titer is often up to or in excess of normal. No such biologic compensatory mechanism exists in the male and the results of castration for breast cancer in the male are more profound and lasting and compare with or even surpass those seen in prostatic carcinoma. Castration seems to be more effectual in the prevention of breast cancer in susceptible strains of mice and when done before the animal reaches maturity cancer rarely develops. This is similar to the observation I have mentioned many times—that it is extremely rare to see carcinoma of the breast in bitches which were spayed young i.e. before their first heat.

It is interesting to note also that the thyrotropic hormone of the pituitary has been used to offset the stimulating effect of estrogenic hormones in cancer susceptible strains of mice. In this connection it should also be recalled that a duct growth hormone, a separate and distinct entity has been isolated by Taylor and Turner (Bureau of Animal Husbandry Veterinary Experimental Station Maryland). Not only does this duct growth hormone increase the development of milk ducts but its effects are so marked in developing the udder in both open and bred heifers that its commercial possibilities in the dairy industry are being investigated.

In the past few years a great deal of interest has been aroused by reports of the milk factor in breast cancer by Bittner and his associates. Research workers in Holland and in Bar Harbor Maine concluded about the same

Fig. 6 Comparison of the incidence of carcinoma in normal breasts and in breast affected by fibrocystic disease. The ratio is 5 to 1

time and independently that transmission of breast carcinoma to the offspring in susceptible mice strains was through the mother and extrachromosomal. With this basic fact in mind, Bittner and his co-workers have shown that in strains of mice susceptible to breast cancer if the litter is allowed to nurse their mother although she has not cancer of the breast the females of the litter develop the disease. If the females of the litter are given over to a foster mother of noncancerous strain they do not develop the disease. It was found also that if these susceptible female offspring nursed their mother only once the lesion developed and only by placing them with a foster mother before they nursed their own mother at all could the disease be prevented and this prevention was absolute. A more striking fact is that by carrying out the experiment in the opposite direction cancer of the breast was implanted in strains of mice having no such susceptibility. A single nursing not only establishes the factor in the young female but in all her descendants and whole races of mice can be saved from developing mammary carcinoma by preventing them from nursing their mother at all.

The milk factor does not produce its effect immediately. It reaches the breast through the intestine apparently increases in quantity as the breasts develop and when the mouse grows old cancer develops in her breast. In the meantime she has transmitted the factor to the females of each successive litter. In some highly susceptible breeds, this happens in every individual. The milk factor is present in large amounts in the breasts of these individuals and although it will not produce the disease directly when injected into other aged individuals one millionth of a gram of mammary tissue yields enough of it when extracted with saline to confer the disease on an endless series of animals. A great deal of experimental

Fig. 3. The American College of Surgeons, 1945 report. Of a total of 7,636 cases there were 57.3 per cent cures. Ten per cent are less than 30 years of age. Best results were obtained in the 35-50 year age group. Poorest results in 50-60 year age group. Heredity as a factor in 30 per cent. Nulliparas numbered more than 1 out of 100.

differentiation. Inasmuch as *each and every* discrete nodule in the breast requires removal aspiration biopsy is an unnecessary procedure. It may when negative confuse the picture and lead to refusal of operation. There is nothing which will replace the satisfaction of getting the gross specimen in one's hand and examining it. I am sure we shall all save more lives that way.

Regarding the etiology of mammary carcinoma, little can be said and less proved. Recently many facts have developed which have led to interesting speculation. The hereditary factor is difficult to evaluate. The impressive experiments of Maud Slye in the inbreeding and outbreeding of cancer mice have been repeated and confirmed by many observers. In the human organ specificity seems to be the most important consideration in heredity and is present in 20 per cent.

The effect of estrogens continues to be stressed and cancer of the breast has been produced in both susceptible and nonsusceptible strains of mice by administering estrogens in

large quantities for prolonged periods. Many clinicians have reported cases of breast carcinoma following prolonged treatment of menopausal women with estrogens in high dosage. While these reports are not conclusive, and while it is a fact that the doses given are far in excess of the physiological titer they are impressive and suggest that great caution should be used and estrogens should not be given to any woman in amounts greater than normally occurring and none at all to women with a family history of carcinoma especially of the breast and none to women who have been operated upon for cancer of the breast nor to any woman with a breast tumor of any kind before or after operation or other treatment.

To the clinician breast stasis and arrest of function continues to be the most important and impressive predisposing factor in the development of breast cancer. The lesion is more common in the nullipara by nearly 2 to 1. Cessation of lactation produces a more profound and complete involutional effect on the human breast than any other factor. In keeping

other operation in surgery in which the result is so directly measured by a knowledge of the anatomy and by the thoroughness and precision of its performance.

X ray and radium are purely ancillary and in no way competitive in the therapy of mammary carcinoma. Cancer of the breast is not radiosensitive nor radioresponsive. All breast cancers (except anaplastic) are radioresistant. Preoperative x ray therapy has been generally abandoned. It did not add to the 5 year 'cures'. It greatly increased the blood loss during the radical operation because of perivascular fibrosis which condition also interfered with the thoroughness of the dissection. Also the incidence and degree of lymphedema of the arm was greatly increased by it. As for postoperative x ray therapy too much has always been expected of it by too many. It is not a substitute for nor an excuse for an incomplete radical dissection. There are three schools of thought regarding postoperative x ray therapy (1) those who do not advise it at all (2) those who advise its use only when axillary nodes are found involved and (3) those who employ it routinely.

All of these groups are composed of both roentgenologists and surgeons sometimes one leading and the other following and vice versa. The first group says in substance 'If the radical operation has been well done what is there to treat? It is like shooting at the hole before the rat pokes his head out, etc. The answer to this group is one word—implants. It has always been my contention that local recurrence in scar or skin flaps is due to implantation of cancer cells by the operator during the operation. By using an antiseptic technique, thin skin flaps and postoperative x ray therapy we have been able to reduce our local recurrences to less than 1 per cent. As high as 27 per cent have been reported in some clinics. The second group—those who advise postoperative x ray therapy only when axillary nodes are involved—apparently presuppose that all the nodes were possibly not removed. It is rare for experienced surgeons to leave nodes and one rarely sees recurrence in the axilla among experienced operators. This policy would seem to shift some of the responsibility from the surgeon—where it all should remain

and on the other hand could possibly be an excuse for a less meticulous radical dissection. We have all heard surgeons say, 'If there is any cancer left the x ray will take care of it. If carcinoma is left in lymph nodes and only 25 per cent can be sterilized by x ray no one should depend on that. As for the third group, those who advise routine postoperative x ray therapy it is unfortunate that a standard rational basis for this plan has not been agreed upon and advocated. I have for many years, advised routine postoperative x ray therapy on the basis that we can and often do accomplish two desiderata i.e. destroy implanted cancer cells thereby avoiding or reducing local recurrences second destroy cancer cells already seeded in the mediastinal pathway en route to hilar nodes and lungs. On this basis we have advocated two different plans of treatment. Believing that implantation can arise only from two possible sources the biopsy site or from the nodes if they are involved and that seeding into the mediastinal lymphatics can occur with or without node involvement, the plan of treatment is varied according to presence or absence of nodes, and in both plans of treatment deep therapy to the mediastinum is included. If no nodes are involved, a superficial soft tissue technique is mapped out, using four portals axillary suprascapular and upper incision middle and lower part of incision mediastinum. To the first three fields are given, tangentially 200 roentgens each time six times to each field a total of 1200 rat units to each. The factors are 140 kilovolts, 3 millimeters aluminum 50 centimeter target distance, 15 by 15 centimeter portals 20 milliamperes $5\frac{1}{2}$ seconds. To the mediastinal pathway deep therapy is given alternating with the other ports and using for the mediastinum 200 to 220 kilovolts, 312 rat units per treatment, 50 to 60 centimeter target distance, 0.5 to 1 millimeter copper filter every fifth day up to about 2100 roentgens.

In the group with node involvement the usual fractionated deep therapy is given using 5 portals suprascapular axillary breast area and center of scar lower incision mediastinum. The same factors and dosage are used to each of these portals as is given to the mediastinum as noted above.

TABLE II.—EFFECT OF EXTENT OF AXILLARY METASTASES ON SURVIVAL*

	Cases	Living and well 5 yrs per cent	Living and well 7-15 yrs per cent	Average survival of those dead of disease years

tion has been done to determine whether tumor susceptibilities in mice besides mammary carcinoma are transferred through breast milk. The results have been negative. There is no evidence of any kind even to suggest that the milk factor is in any way applicable to the human. Surveys are now under way at the University of Minnesota and the University of Ohio which, in a decade, may give us some light on this possibility. Although not directly inducing the disease, the possibility of the milk factor being a virus has greatly revived and stimulated interest in the virus theory of tumors. With the new electron microscope and the recently developed ultraviolet lighting method (Caspar of Sweden) amazing and beautiful pictures have been made from thin tissue cultures showing not only cell fission and mitosis but clearly showing the virus in the cell protoplasm. By these methods, virus has been demonstrated clearly in the cells of chicken sarcoma, in the large papillomas of the Western cotton tail rabbit and in the cells of

hypernephroma to which the leopard frog of the marishes is so susceptible.

TREATMENT

In the treatment of breast cancer radical operation holds first place. The percentage of 5 year cures and the duration of life of those not cured are inversely proportional to the percentage of node involvement (Tables II and III). This is the most significant single fact for consideration in the therapy of breast cancer and the fact that makes the thorough, meticulous, systematized radical dissection of paramount importance.

For the past 24 years in my breast clinic, it has been my custom to count the nodes removed, to determine the percentage of malignant involvement and note their location. The radical operation is done in such a way that the layers of fascia can be spread out in sheets, and the nodes counted by hand lens and palpation by the pathologist. The layers are numbered and the number of nodes, per cent involved, and location are included in the pathologist's report. Thus we have found not only of definite prognostic value but a practical guide in the after care and follow up of individual cases.

Every now and then all of us are confronted in consultation or in conference by a medical man or a surgeon who states that the radical operation is unnecessary, that just as good results can be obtained with simple mastectomy plus x ray therapy. This statement should be immediately challenged and vigorously refuted. To accept it is to set breast surgery back more than 80 years to the time before Charles Hewitt Moore (the father of modern breast surgery). The facts are that x ray will sterilize the breast in only one third—33 per cent. When cancer is confined to the breast the radical operation gives 70 to 80 per cent 5 year cures. X ray will sterilize involved axillary nodes only in 1 out of 4—25 per cent. The results of radical operation in those cases with axillary node involvement is 48 per cent 5 year cures. At present, radical operation certainly represents our best and most reliable means of combating this disease and whatever disrepute has fallen upon it is most often due to the hurried incomplete performance of it. There is no

other operation in surgery in which the result is so directly measured by a knowledge of the anatomy and by the thoroughness and precision of its performance.

X ray and radium are purely ancillary and in no way competitive in the therapy of mammary carcinoma. Cancer of the breast is not radiosensitive nor radioresponsive. All breast cancers (except anaplastic) are radioresistant. Preoperative x ray therapy has been generally abandoned. It did not add to the 5 year 'cures.' It greatly increased the blood loss during the radical operation because of perivascular fibrosis which condition also interfered with the thoroughness of the dissection. Also the incidence and degree of lymphedema of the arm was greatly increased by it. As for postoperative x ray therapy too much has always been expected of it by too many. It is not a substitute for nor an excuse for an incomplete radical dissection. There are three schools of thought regarding postoperative x ray therapy (1) those who do not advise it at all (2) those who advise its use only when axillary nodes are found involved and (3) those who employ it routinely.

All of these groups are composed of both roentgenologists and surgeons, sometimes one leading and the other following and vice versa. The first group says in substance: If the radical operation has been well done what is there to treat? It is like shooting at the hole before the rat pokes his head out etc. The answer to this group is one word—implants. It has always been my contention that local recurrence in scar or skin flaps is due to implantation of cancer cells by the operator during the operation. By using an antiseptic technique thin skin flaps and postoperative x ray therapy we have been able to reduce our local recurrences to less than 1 per cent. As high as 27 per cent have been reported in some clinics. The second group—those who advise postoperative x ray therapy only when axillary nodes are involved—apparently presuppose that all the nodes were possibly not removed. It is rare for experienced surgeons to leave nodes and one rarely sees recurrence in the axilla among experienced operators. This policy would seem to shift some of the responsibility from the surgeon—where it all should remain

and on the other hand could possibly be an excuse for a less meticulous radical dissection. We have all heard surgeons say "If there is any cancer left the x ray will take care of it." If carcinoma is left in lymph nodes, and only 25 per cent can be sterilized by x ray no one should depend on that. As for the third group those who advise routine postoperative x ray therapy, it is unfortunate that a standard rational basis for this plan has not been agreed upon and advocated. I have, for many years advised routine postoperative x ray therapy on the basis that we can and often do accomplish two desiderata: i.e. destroy implanted cancer cells thereby avoiding or reducing local recurrences; second, destroy cancer cells already seeded in the mediastinal pathway en route to hilar nodes and lungs. On this basis we have advocated two different plans of treatment. Believing that implantation can arise only from two possible sources: the biopsy site, or from the nodes if they are involved and that seeding into the mediastinal lymphatics can occur with or without node involvement the plan of treatment is varied according to presence or absence of nodes, and in both plans of treatment deep therapy to the mediastinum is included. If no nodes are involved, a superficial soft tissue technique is mapped out, using four portals: axillary, suprascapular and upper incision, middle and lower part of incision, mediastinum. To the first three fields are given tangentially 200 roentgens each time six times to each field a total of 1200 rat units to each. The factors are 140 kilovolts 3 millimeters aluminum 50 centimeter target distance, 15 by 15 centimeter portals 20 milliamperes $5\frac{1}{2}$ seconds. To the mediastinal pathway deep therapy is given alternating with the other ports and using for the mediastinum 200 to 220 kilovolts 312 rat units per treatment 50 to 60 centimeter target distance, 0.5 to 1 millimeter copper filter every fifth day up to about 2100 roentgens.

In the group with node involvement the usual fractionated deep therapy is given using 5 portals: suprascapular, axillary, breast area and center of scar, lower incision, mediastinum. The same factors and dosage are used to each of these portals as is given to the mediastinum as noted above.

In the treatment of inoperable carcinoma of the breast, simple mastectomy x ray therapy and testosterone are our mainstays—simple mastectomy to avoid or get rid of a foul sloughing mass and improve the patient's condition and morale x ray and testosterone for palliation. It is amazing what can be done in relief and prolongation of life, and here, x ray therapy really comes into its own and most of us frequently find ourselves with a few of our inoperables comfortably outliving some of our 5 year cures.

Castration in the therapy of breast cancer has much more historical interest than practical value. The most that can be said for it is that it has slight temporary effect for a short time in a few cases. In fact the effect of castration is slight and inconsequential compared to the involution caused by cessation of lactation. But ever so often since Schunzinger suggested castration for breast cancer in 1889 and since its performance in 8 cases by Beatson in 1896 it has been revived, tried and abandoned again and again. All the statistical evidence by a comparison of series large and small with and without castration shows it to be of little or no value. If it has any value at all it is in cases of diffuse and advanced bone metastases with high alkaline serum phosphatase. X ray and testosterone however will do more for these cases than x ray and castration. Castration has been advocated to prevent pregnancy to protect the remaining breast, to prevent local recurrences and distant metastases. Pregnancy can be satisfactorily controlled with modern contraceptives. Tubal ligation is justifiable if other methods are objectionable. Surely no woman who has had a radical operation or other treatment for breast cancer should be allowed to become pregnant. The fate of the remaining breast is largely in the hands of the surgeon who does the radical operation. If he removes all the presteral fascia and destroys the superficial transmammary pathway the remaining breast is safe because this is the only direct lymphatic connection. Remembering that 2 per cent of breast cancer is initially bilateral, and that 5 per cent will become bilateral this is an important consideration. As for local recurrences, they can to a large extent be avoided, and as for distant

metastases, they have usually been needed before operation although not demonstrable by examination or x ray. Postoperative x-ray therapy especially to the mediastinum, is our only defense. In the middle 1930's, when x ray therapy was having its revival in the treatment of breast carcinoma, both in the Scandinavian clinics and in the United States, castration by x ray was added to the preoperative therapy. This entire plan has been discarded having been found to be of no help and to have many disadvantages.

In cancer of the male breast castration is much more beneficial and the results far more striking. In fact the male, having no such compensatory gonadal mechanism, the results are comparable to or even surpass those seen in carcinoma of the prostate. In all advanced breast cancer in the male especially with bone metastases, it is a valuable addition to the therapy.

Carcinoma of the breast during pregnancy presents a serious and often hazardous problem. The changes in the breast preparatory to lactation the enormous increase in glandular and ductular elements, the increased blood supply and the increased stimulation both by estrin and prolactin all make for rapid fulminant growth. Also the type and grade of cancer is usually duct or adenocarcinoma, grade 2 or 3. This fact adds to the rapid advance. No progress can be expected in the arrest or treatment of the breast lesion while the pregnancy exists. If it is less than 5 months and the breast lesion is still operable the pregnancy should be interrupted at once testosterone given daily in large doses and the radical operation with adequate transfusions should be done as soon as the patient's condition permits. If the pregnancy is beyond 5 months and the breast lesion operable, hysterotomy tubal ligation transfusions and radical operation should be the plan. Testosterone will be of great value but castration should be avoided because it will destroy the balance between estrin and prolactin and the resultant pituitary ascendancy will increase lactation or the preparation therefor.

In the late weeks of pregnancy if the breast lesion is operable cesarean section with an attempt at a viable child should be followed as

soon as possible with the radical operation transfusions, testosterone etc. If the lesion is frankly inoperable a week or two of added fetal maturity may be permissible the delivery to be followed by simple mastectomy testosterone and x ray therapy. Each case should be carefully analyzed and individualized the question of operability and the saving of the mother by the radical operation being the primary consideration and the question of a viable child coming into first consideration only in the late weeks or in the obviously inoperable.

Special problems in the therapy of mammary carcinoma are also presented by Volkmann's inflammatory carcinoma (mastitis carcinosa) anaplastic carcinoma of the breast and perhaps by duct carcinoma in young women.

In mastitis carcinosa, the brawny red edematous erysipeloid lesion not only spreads rapidly along the superficial lymphatics but quickly penetrates the breast through the interlobular lymphatics to involve the pectorals and fascia. Growth and penetration are usually so rapid that the lesion is soon beyond the hope of surgery which spreads the disease and hastens the end the average duration of life being 6 to 8 months. The widespread involvement often results in cancer *en chiasse*. If seen early the best palliative procedure is in terstitial radiation the so called radical radi um needling (Keynes pattern).

Anaplastic carcinoma of the breast is often badly handled surgically with poor results. By the time the nodule reaches palpable size bone metastases have occurred in many instances, but fortunately both the primary lesion and the bone metastases are highly radiosensitive and radiotherapy is the treatment of choice. This is the only radioresponsive breast lesion.

Duct carcinoma in young women deserves special mention because of the pessimism and defeatist attitude regarding mammary cancer in the young. For this attitude there is no basis. Only 2 per cent of breast carcinoma occurs before 30 years of age and the best results of radical operation are obtained from 35 to 50 years of age. The points that should be stressed in the younger group are two. This is the age of active cyclic changes in the breast

and of fibrocystic disease and these women are more likely to become victims of cancer. Second young women with active breasts usually develop one of the more rapidly growing types of cancer—adenocarcinoma or duct carcinoma grading 2 or 3—and not sarcoma. Early diagnosis is imperative but while still operable the results compare favorably with the same type and grade in the older group. If testosterone has any place in prophylaxis against recurrence after radical operation it is in these young women with grade 2 or 3 growths. Castration *should be avoided*. It will give the whip hand to the pituitary by removing its biologic antagonist estrin. Prolactin the luteotrophic hormone of the pituitary is much more to be feared. Testosterone will suppress it most satisfactorily.

CAUSES OF FAILURE

Although the facts and figures definitely justify an optimistic realism in the problem of breast carcinoma, it is always of value and interest to review our causes of failure critically.

1 Late diagnosis. Early diagnosis will alone save 4 000 additional lives in the United States each year (Fig 5).

2 Failure to recognize inoperability as follows (a) supraclavicular nodes (b) fixation of axillary nodes (c) fixation of the breast on chest wall (d) distant metastases, to lung liver bones (e) widespread parietal dissemination—diffuse secondary subcutaneous nodules (f) mastitis carcinosa Volkmann's inflammatory carcinoma (g) cancer *en chiasse* (h) anaplastic carcinoma (i) incurable constitutional diseases which may lead to fatality. This is particularly in the aged group cardiac, cardiorenal etc. in which the radical operation would be hazardous, and the life expectancy with simple mastectomy would equal that of the complicating disease.

Under inoperability we should frankly discuss the one most discouraging feature of breast surgery the factor which I have for many years, called *preseeding* to emphasize its importance to my graduate students. We have found in our follow up clinics, that in spite of careful preoperative examination which routinely includes an x ray survey of chest spine ribs and pelvis in 11 per cent of

our cases the patient returns within 2 years with a distant metastasis which must have been seeded prior to the radical operation. This *preseeding* gives no clue whatever of its existence either in symptoms, physical signs, or x ray evidence. Its possibility always exists. The more advanced the lesion the greater the percentage of node invasion the more of a possibility it becomes. It can and does occur without axillary node involvement although infrequently. This is not surprising if we recall that 4 of the 8 pathways of spread do not traverse the nodes (mediastinal transmammary epigastric, superficial abdominal). The discouraging feature is that we are almost defenseless against *preseeding*. Our only defense is x ray therapy to the mediastinum as a part of our routine postoperative program. All 4 of the other outside pathways are included in the x ray therapy fields as a routine measure.

3 Inadequate and incomplete radical operation. Unfortunately some surgeons, although skilled in their fields, seem to regard the radical breast dissection as just another operation

a task to be quickly completed. Speed has no place in this work. Others, engrossed in anatomical and technical detail, take no precaution whatever against implantation. Unless one is cancer cell minded disastrous consequences follow. Other common errors of technique are failure to remove the superficial fascia from the skin flaps and to remove the epigastric and subscapular node groups.

4. Pessimism and defeatism as a cause of failure, are not justified by the facts and figures and are too often due to a lack of knowledge of them. There is no place in breast surgery for the defeatist and nothing to support him.

SUMMARY

Although cancer of the breast is increasing annually the cure rate is increasing more rapidly than the incidence. "Fight Cancer with Knowledge" can be applied to the medical profession as well as to the laity. Nowhere in the realm of surgery is it so true that 'Knowledge is Power' as it is in breast cancer and in this instance it often means power to save lives.

LABORATORY AND CLINICAL EXPERIENCES WITH STREPTOMYCIN THERAPY IN THE MANAGEMENT OF INFECTIONS OF INTESTINAL ORIGIN

HENRY L. SILVANI M.D., SANFORD ROTHENBERG M.D., HELEN WARMER, A.B.
JOYCE AMLUXEN A.B., and H. J. McCORKLE, M.D. San Francisco California

DURING the past 6 months careful clinical and laboratory studies have been made on 13 patients with serious intra abdominal infections who have received streptomycin therapy (Table I). Five were patients with acute diffuse peritonitis, 6 had intra abdominal abscesses, 1 acute cholangitis and 1 an abscess of the liver. Streptomycin was given by intramuscular injection at 3 hour intervals in all cases. The patients with diffuse peritonitis each received from 24 to 52 grams of streptomycin over periods of 8 to 14 days (2.7 to 4 grams daily). The other patients each received from 15 to 48 grams of streptomycin over periods of 5 to 16 days (3 to 4 grams daily). Other chemotherapy was discontinued during the period of treatment with streptomycin in all except 2 cases, in which penicillin and streptomycin were given concurrently. Since most of these patients were seriously or critically ill with infection they received, in addition to the chemotherapy supportive fluids and transfusions, continuous aspiration of the stomach and upper intestinal tract when necessary, and surgical procedures for removal or drainage of septic foci when indicated.

CASE 1. After an acute illness of 30 hours duration a woman 33 years of age was found to have a diffuse peritonitis originating from a gangrenous perforated appendix. Appendectomy with drainage of the abdominal wound was done. Bacteria cultured from the peritoneal exudate were *Escherichia coli* and beta hemolytic streptococci. These organisms were susceptible *in vitro* to 4 to 5 units of streptomycin per cubic centimeter (a concentration within the blood streptomycin level obtained with the dosage used). Streptomycin therapy was started immediately after operation. The patient received 24 grams

of streptomycin over a period of 9 days (2.7 grams daily). The patient convalesced satisfactorily. She became afebrile on the 6th postoperative day and the wound healed without infection by the 14th postoperative day. It is possible but doubtful that streptomycin therapy contributed to the recovery of this patient.

CASE 2. After an acute illness of 36 hours duration a man 18 years of age was found to have a diffuse peritonitis originating from a gangrenous perforated appendix. Appendectomy was performed. Bacterial cultures made from the peritoneal exudate contained *Escherichia coli* and staphylococci (type). *In vitro* these organisms were resistant to streptomycin in concentrations up to 150 units per cubic centimeter (a concentration considerably above the blood levels obtainable with the dosage and method of administration used). The patient received 33.4 grams of streptomycin over a period of 8 days (3 grams daily). All symptoms of diffuse peritonitis subsided rapidly. The patient was afebrile by the 3th postoperative day and the abdominal wound healed without infection in 12 days. It appears unlikely that streptomycin contributed to recovery in this case.

CASE 3. A man 67 years of age gave a history of lower abdominal pain of 15 hours duration and showed signs of peritonitis. Laparotomy revealed a perforated diverticulum of the sigmoid colon and diffuse peritonitis. Three hours after operation streptomycin therapy was started. He received 27 grams (2.7 grams daily) over a period of 10 days. Unfortunately the culture tube was broken so that bacteriological data could not be obtained. Postoperatively the patient remained acutely ill and febrile and the laparotomy incision became infected. After 10 days streptomycin therapy was discontinued and penicillin and sulfonamide therapy started. Within 12 hours after therapy was changed the patient was afebrile. Obviously streptomycin therapy was of no value in this case.

CASE 4. An elderly woman was acutely ill for 16 days with generalized abdominal pain, vomiting and jaundice. Chemotherapy with penicillin and sulfadiazine had no appreciable effect on the course of her illness. She appeared moribund. Streptomycin therapy was started, 4 grams daily being given. After 24 hours of streptomycin treatment the patient's condition improved remarkably and an operation was performed. A diffuse peritonitis due to perforation of the common bile duct by a calculus was found. Bac

From the Department of Experimental Surgery of the University of California Medical School. This project received financial support from the Christine Breon Fund. Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, December 1946.

Fig. 1 Diagram indicating method of producing diffuse experimental peritonitis of appendiceal origin. The vascular supply is divided, the base of the appendix is ligated, the appendix is crushed, and the spleen and omentum are removed.

there was purulent drainage from the laparotomy wound. Bacterial cultures contained *Escherichia coli* (susceptible to 285 units of streptomycin per cubic centimeter) and a nonhemolytic *Staphylococcus aureus* (susceptible to 200 units of streptomycin per cubic centimeter). He was given 3 grams of streptomycin daily for 10 days (a total of 30 grams). During this course of treatment the patient's condition improved and the drainage from the wound ceased. However, this result must be considered to be doubtful because the patient had previously had many similar remissions with temporary closure of the wound.

CASE 10. A 25 year old woman had been acutely ill with tubo-ovarian abscesses for 4 months. In spite of two operations for drainage of abscesses she remained acutely febrile and became progressively worse. Cultures made from the abscesses contained *Escherichia coli* nonhemolytic, *Staphylococcus albus*, *Pseudomonas aeruginosa* and alpha hemolytic strep-

tococcus. She was treated with 3 grams of streptomycin daily for 16 days (a total of 48 grams). The *Escherichia coli* and *Pseudomonas aeruginosa* disappeared from her cultures but the clinical course of the disease continued progressively downhill. Streptomycin therapy did not help in this case.

CASE 11. A woman 48 years old developed a pelvic peritonitis and abscess after repair of a rectovaginal fistula. Bacterial cultures contained hemolytic *Staphylococcus albus*. She had been acutely ill and febrile for 14 days before streptomycin therapy was started. She received 3 grams of streptomycin daily for 14 days (a total of 42 grams). Her temperature dropped from 103 degrees F. to normal during streptomycin therapy. Streptomycin therapy may have been helpful in this case but it is doubtful.

CASE 12. A man 47 years of age had a history of many episodes of acute cholangitis following an operation for removal of stones from the common bile duct. He entered the hospital with an attack of up-

TABLE I—CLINICAL USE OF STREPTOMYCIN

Case	Diagnosis	Source of Infection	Bacteriology	Amount of streptomycin, gm	Effects of streptomycin
	Diffuse peritonitis	Perforated acute appendicitis	<i>Escherichia coli</i> , beta hemolytic streptococcus	24	Doubtful, but possibly beneficial
	Diffuse peritonitis	Perforated acute appendicitis	<i>Escherichia coli</i> , staphylococcus type undetermined	23	Doubtful
	Diffuse peritonitis	Sigmoid diverticulitis	No cultures obtained	27	Of no value
	Diffuse peritonitis	Perforated common bile duct	<i>Escherichia coli</i> , proteus vulgaris, streptococcus (fecalis)	36	Probably beneficial
3	Diffuse peritonitis	Perforated amebic ulcer of colon	No cultures obtained	51*	Possibly beneficial
6	Abdominal abscess (pelvic)	Colon resection with anastomosis	No cultures obtained	24	Of no value
	Abdominal abscess	Colon resection with anastomosis	<i>Escherichia coli</i> , beta hemolytic streptococcus, alpha hemolytic streptococcus	33	Of no value
8	Abdominal abscess	Regional ileitis	<i>Escherichia coli</i> , streptococcus viridans, clostridium welchii	36	Doubtful
	Abdominal abscess	Sigmoid diverticulitis	<i>Escherichia coli</i> , nonhemolytic staphylococcus	30	Doubtful
10	Abdominal abscess	Pelvic inflammatory disease	<i>Escherichia coli</i> , nonhemolytic staphylococcus albus, alpha hemolytic streptococcus	6	Of no value
	Abdominal abscess (pelvic)	Rupture of retrovaginal bolus	Hemolytic staphylococcus albus	4	Doubtful, but possibly beneficial
	Acute cholecystitis	Common bile duct stricture	No cultures obtained	15*	Doubtful
	Hepatic abscess	Hematomatous	Beta hemolytic streptococcus, Bacteroides	24	Doubtful

*Combined with penicillin therapy.

teriological cultures made from the peritoneal exudate showed the presence of *Escherichia coli*, *Proteus vulgaris*, and *Streptococcus fecalis*. *In vitro* laboratory determination indicated that the *Escherichia coli* and *Streptococcus fecalis* were susceptible to concentrations of 40 units of streptomycin per cubic centimeter and the *Proteus vulgaris* was susceptible to 20 units of streptomycin per cubic centimeter. A total of 36 grams of streptomycin was given over a period of 9 days. The patient recovered. Streptomycin therapy probably was beneficial in this case.

CASE 5. A woman 35 years of age had been ill with amebic colitis for 3 weeks when she suddenly developed severe abdominal pain and signs of diffuse peritonitis. It was believed that she had a perforation of an amebic ulcer of the colon. She had been acutely ill with peritonitis for 5 days and appeared moribund before antibiotic therapy was started. No cultures were obtained. She received 4 grams of streptomycin and 400,000 units of penicillin daily for 14 days. She improved slowly and recovered. Streptomycin therapy may possibly have been of some value in this case.

CASE 6. A woman 40 years of age developed a pelvic abscess after resection and anastomosis of the pelvic colon. She was febrile and acutely ill for 15 days before streptomycin therapy was begun. She received 3 grams of streptomycin daily for 8 days, a total of 24 grams, without apparent benefit. After a colostomy and surgical drainage of the abscess were

done she recovered rapidly. Streptomycin therapy obviously had effect in this case.

CASE 7. A 66 year old man developed an abdominal abscess with a draining wound 3 months after resection and anastomosis of the colon. Cultures contained *Escherichia coli* (susceptible to 7.1 units of streptomycin per cubic centimeter) beta hemolytic streptococcus (susceptible to 2.5 units of streptomycin per cubic centimeter) and alpha hemolytic streptococcus (susceptible to 0.2 unit per cubic centimeter). He had been ill for 2 months when streptomycin therapy was instituted. He was given 3 grams of streptomycin daily for 11 days (a total of 33 grams) without apparent benefit.

CASE 8. A 25 year old woman had been ill with regional ileitis for 7 years. An operation was performed for resection of the diseased intestine and drainage of abdominal abscesses. Bacterial cultures demonstrated *Escherichia coli*, *Streptococcus viridans*, and *Clostridium welchii*. Streptomycin therapy was started on the first postoperative day. Four grams of streptomycin were given daily for 9 days (a total of 36 grams). The patient became afebrile in 3 days. Wound drainage diminished rapidly and the wound closed in 10 days. It is doubtful that streptomycin contributed to recovery in this case.

CASE 9. A man 44 years of age was found on exploratory laparotomy to have an abdominal abscess associated with diverticulitis of the sigmoid colon. Six months later the abscess was still present and

there was purulent drainage from the laparotomy wound. Bacterial cultures contained *Escherichia coli* (susceptible to 285 units of streptomycin per cubic centimeter) and a nonhemolytic *Staphylococcus aureus* (susceptible to 200 units of streptomycin per cubic centimeter). He was given 3 grams of streptomycin daily for 10 days (a total of 30 grams). During this course of treatment the patient's condition improved and the drainage from the wound ceased. However, this result must be considered to be doubtful because the patient had previously had many similar remissions with temporary closure of the wound.

CASE 10. A 25-year-old woman had been acutely ill with tubo-ovarian abscesses for 4 months. In spite of two operations for drainage of abscesses she remained acutely febrile and became progressively worse. Cultures made from the abscesses contained *Escherichia coli*, nonhemolytic *Staphylococcus albus*, *Pseudomonas aeruginosa*, and alpha hemolytic strep-

tococcus. She was treated with 3 grams of streptomycin daily for 16 days (a total of 48 grams). The *Escherichia coli* and *Pseudomonas aeruginosa* disappeared from her cultures, but the clinical course of the disease continued progressively downhill. Streptomycin therapy did not help in this case.

CASE 11. A woman 48 years old developed a pelvic peritonitis and abscess after repair of a rectovaginal fistula. Bacterial cultures contained hemolytic *Staphylococcus albus*. She had been acutely ill and febrile for 14 days before streptomycin therapy was started. She received 3 grams of streptomycin daily for 14 days (a total of 42 grams). Her temperature dropped from 103 degrees F to normal during streptomycin therapy. Streptomycin therapy may have been helpful in this case, but it is doubtful.

CASE 12. A man 47 years of age had a history of many episodes of acute cholangitis following an operation for removal of stones from the common bile duct. He entered the hospital with an attack of up-

Fig. 1. Blood and peritoneal streptomycin level following single intramuscular dose of 0.33 gram of streptomycin (dog).

per abdominal pain, chills (40°C) and icterus of 48 hours duration. Blood cultures produced no bacterial growth. Penicillin therapy was given for 1 day pending the arrival of streptomycin. On the third day of his illness a few hours after his temperature had subsided to normal streptomycin therapy was started. He received 3 grams of streptomycin daily for 3 days (total amount 15 grams). The patient recovered completely from this attack of cholangitis but improvement began a few hours before streptomycin therapy was started therefore, its value in this case must be considered as doubtful.

CASE 13. A man 48 years of age had been ill for 2 months with chills, fever, sweats and upper abdominal pain. An abscess of the liver was drained and bacterial cultures of the pus contained beta hemolytic streptococcus and Bacteroides (*In vitro* tests indicated resistance of these organisms to streptomycin in concentrations as high as 2,000 units per cubic centimeter). After drainage of the abscess, the patient was given 3 grams of streptomycin daily for a period of 8 days (a total of 24 grams). The Bacteroides soon disappeared but the streptococcus persisted for some time in the cultures. The patient re-

TABLE II.—STREPTOMYCIN SUSCEPTIBILITY OF BACTERIA CULTURED FROM PERITONEAL EXUDATE OF ANIMALS WITH EXPERIMENTAL PERITONITIS OF APPENDICEAL ORIGIN

Organism	Effective concentration of streptomycin (units/c)

covered completely. It appears doubtful that streptomycin therapy was helpful in this case.

It was difficult to evaluate, from these clinical studies, the effect of streptomycin therapy on intra abdominal infections. In order to obtain more information regarding the value of streptomycin a group of surgical laboratory experiments was undertaken.

Fulminating diffuse peritonitis was produced in dogs by a modification of the method of Bower described previously (8). This consisted of dividing the blood supply to the appendix, ligating the base with umbilical tape, crushing the wall of the appendix and removing the omentum and spleen (Fig. 1) and administering 60 cubic centimeters of castor oil by gavage. All animals received supportive therapy consisting of parenteral fluids and electrolytes throughout the postoperative period. A small soft rubber tube was brought out through the abdominal incision from which peritoneal fluid was withdrawn for bacterial cultures, and in two groups of animals streptomycin was instilled locally through these tubes. In most of the animals the tubes functioned satisfactorily but occasionally the animal would withdraw the tube before the experiment was completed. *In vitro* streptomycin susceptibility tests of bacteria cultured from the peritoneal exudate of animals with experimental peritonitis are shown in Table II. Thirty five animals were used for the experiment. Ten served as untreated controls, 10 animals received systemic streptomycin therapy beginning 6 hours postoperatively and 10 received local streptomycin

TABLE IV.—EXPERIMENTAL PERITONITIS—SYSTEMIC STREPTOMYCIN THERAPY BEGUN 6 HOURS POSTOPERATIVELY

Dosage—33 gram of streptomycin intramuscularly every 4 hours—2.0 grams daily	
Number of animals	10
Survived	0
Died	9
Average period of survival	92 hours

*One animal developed fecal fistula apparently after surviving the original period of acute diffuse peritonitis.

Bacteria cultured	6 hours postoperative therapy (7 animals)	% necropsy (9 animals) (Incidence)
<i>Escherichia coli</i>	6	9
<i>Enterobacter vulgaris</i>	0	0
<i>Bacteroides</i>	1	0
<i>Aerobac sporeformis</i> <i>g. bacillus</i>	1	1
<i>Clostridium</i>	5	8

therapy The animals receiving systemic streptomycin therapy were given 2 grams of streptomycin daily (33 gram every 4 hours) by the intramuscular route. Figure 2 shows relative blood and peritoneal streptomycin levels following a single intramuscular dose of 0.33 gram of streptomycin.

All of the 10 untreated control animals died with diffuse peritonitis. The average period of survival was 39 hours. The organisms cultured from the peritoneal fluid of the untreated control series are shown in Table III.

Of the group of 10 animals that received systemic streptomycin therapy beginning 6 hours postoperatively 9 died and 1 survived. One of the animals that died apparently survived the period of acute diffuse peritonitis but developed a fecal fistula with overwhelming infection. The average period of survival of the animals that died with diffuse peritonitis was 3 days 20 hours. It is interesting that the bacterial organisms cultured from the peritoneal fluid 6 hours after the onset of peritonitis generally were the same types and in roughly similar proportion to those cultured from the peritoneal fluid at necropsy (see Table IV).

TABLE V.—EXPERIMENTAL PERITONITIS—SYSTEMIC STREPTOMYCIN THERAPY BEGUN IMMEDIATELY POSTOPERATIVELY

Dosage—33 gram of streptomycin intramuscularly every 4 hours—2.0 grams daily

Number of animals	5
Survived	0
Died	5
Average period of survival	75 hours

Bacteria cultured	6 hours postoperative therapy (4 animals) (Incidence)	% necropsy (5 animals) (Incidence)
<i>Escherichia coli</i>	2	3
<i>Bacteroides</i>	0	1
<i>Clostridium</i>	3	4

<i>Alpha hemolytic streptococcus</i>						4
<i>Gamma streptococcus</i>						—
<i>Streptococcus fecalis</i>						—
<i>Nonhemolytic staphylococcus aureus</i>						—

Necropsy findings: Diffuse peritonitis

All animals receiving systemic streptomycin therapy were acutely ill and toxic. Their appearance was identical with that of the untreated control animals.

Five animals received 0.4 gram of streptomycin intraperitoneally (through a small rubber tube) twice on the day of operation and once daily thereafter. All 5 animals died of diffuse peritonitis. The average period of survival was 3 days 15 hours. The bacterial flora was not significantly altered by this therapy (see Table VI).

Five animals received intraperitoneal stillations of 4.0 grams of streptomycin beginning immediately after operation twice on the day of operation and at 24 hour intervals thereafter. Bacterial cultures made after a period of 6 hours and again at necropsy indicated that doses of 4.0 grams intraperitoneally effectively sterilized the peritoneal fluid in 4 of 5 animals. Cultures of the peritoneal fluid of the remaining animal showed the presence of *Escherichia coli* and *Clostridium welchii*. However animals treated with such large doses of streptomycin intraperitoneally in variably died of streptomycin intoxication with respiratory failure, apparently of central origin.

SUMMARY

A group of 13 patients with serious intra-abdominal infections was treated with systemic streptomycin therapy. The result of streptomycin therapy was believed to be probably beneficial in 1 case, possibly beneficial in 1 case, doubtful but possibly helpful in 2, of doubtful value in 5 and of no value in 4 cases.

In a series of animals in which fulminating diffuse peritonitis of appendiceal origin was produced, systemic and local streptomycin therapy in dosages used apparently prolonged the lives of the animals, but did not significantly alter the bacterial flora of the peritoneal exudate or save the lives of the animals.

THE MICROSCOPIC CRITERIA FOR THE DIAGNOSIS OF EARLY CARCINOMA OF THE CERVIX UTERI

EUGENIA E. GURSKIS M D DONALD C BEAVER M D and
HARRY M NELSON M D F A C S Detroit Michigan

ONE of the first papers on early non-invasive carcinoma of the cervix uteri was written by Rubin and appeared in 1910. It contained the report of 3 cases in which the diagnosis was made by the presence of atypical cells and loss of cellular polarity confined to the surface squamous epithelium. This author reached the conclusion that the diagnosis of early carcinoma depended upon these microscopic cell changes and that a pathological diagnosis of cancer in the preclinical preinvasive stage was possible. Schuller in 1933 described the early malignant changes of squamous epithelium of the cervix uteri as consisting of the presence of nuclei up to the surface of the epithelium, the presence of atypical and polymorphic cells especially as regards the nuclei, a sharply demarcated basal layer against the underlying connective tissue, and a distinct, oblique line of demarcation between the normal and carcinomatous cells. Meyer in 1941 described these changes as an increase of nuclear chromatin, enlargement of nuclei, loss of regular layering, and a 45 degree angle at the junction between normal and carcinomatous tissue. Using epithelium of the skin Broders previously in 1932 had identified the changes of early carcinoma as consisting of an increase in size and irregularity of the cells, more basophilic nuclei, atypical mitoses, and occasional grouping of the cells as tumor giant cells. He found that invasion was not necessary for a diagnosis of malignancy.

SELECTION OF MATERIAL FOR STUDY

This study was made by obtaining the cervixes from the microscopic slide files of the laboratory of Woman's Hospital over a period of approximately 10 years, and from the services of Dr. Mark Maun and Dr. Lawrence

Berman of the department of pathology of Wayne University College of Medicine Detroit. Cervices numbering 4,054 were selected from the files of Woman's Hospital which revealed benign lesions including hypertrophy, hyperplasia, metaplasia, leucoplakia, parakeratosis, hyperkeratosis, polyps, lacerations, scars, ulcerations, erosions, cervicitis, endocervicitis, and so called precancerous changes of the cervix. The stratified squamous epithelium of the portio vaginalis was the particular point of study since it is from this area that 95 per cent of all cervical carcinomas arise.

METHOD OF STUDY

From these 4,054 cases 7 were selected, containing early noninvasive carcinoma. Eight additional cases were obtained from other institutions for a total of 15 cases (Table I). Of these 15 cases 6 of early noninvasive carcinoma also demonstrated early invasive carcinoma in other areas of the same cervix. These 6 cases were included in the study for comparison with the early noninvasive lesions.

The cervixes were studied microscopically for changes in cell morphology of the surface stratified squamous epithelium specifically compared with normal cervixes or cervixes revealing benign lesions. Paraffin section technique and hematoxylin-eosin staining were employed. The stage of early squamous cell carcinoma in the preclinical noninvasive stage is thus particularly emphasized. This stage of early carcinoma is referred to by some authors (3) as intraepithelial carcinoma or as carcinoma *in situ* by others (1). In this stage the changes were observed microscopically rather than grossly and were present chiefly in the surface squamous epithelium. No clinical follow up has been pursued to indicate the accuracy of the observations. Only microscopic comparison with early invasive carcinoma and

+denotes the condition indicated as present
mild, —moderate; marked

stages of invasive or clinical carcinoma forms the basis of the study. The squamous epithelium of the portio vaginalis consists normally of two layers namely the stratum germinativum, several cells in thickness and the basal layer one cell in thickness. The cells of the stratum germinativum are rather large and polyhedral with round nuclei staining with a moderate intensity and with a considerable amount of cytoplasm. These cells are rather regularly spaced and appear to be in horizontal parallel rows. The more peripheral cells become somewhat flattened horizontally and appear larger and contain more cytoplasm. The cells of the basal layer are smaller than those of the stratum germinativum and contain a smaller amount of cytoplasm. The nuclei are small, round to oval stained deeply and the cells are placed parallel to one another more or less perpendicular to the cells of the stratum germinativum.

DISCUSSION OF CASES

The most characteristic finding of the squamous epithelium indicating departure from normal toward malignant transformation, was the presence of deeply stained (hyperchromatic) oval nuclei. This characteristic was always present and was diagnostic however it was found to exist to a varying degree. As a rule, the density of the nuclear stain was not as great in the earliest stages as exemplified by Case 1 (Fig. 1). Occasionally variations in the nuclear staining and size could be seen in the same cervix. For example, in Case 2 (Fig. 2) in one area the nuclei were deeply stained and large while in another area they were smaller and even darker stained. In Case 4 (Fig. 5) the nuclei appeared more or less uniformly oval and dark.

Decreased amount of cytoplasm in the epithelial cells was observed almost as often in frequency as the nuclear changes. This find

Fig. 1. Case 1. This case reveals an extremely early carcinoma of the cervix with abrupt demarcations from the normal epithelium on each side of the lesion $\times 65$.

ing was more pronounced in the advanced cases. In Case 1 (Fig. 1) the cytoplasm was mildly decreased in amount and was more marked in the cells nearest the basal layer. All the other cases revealed a marked decrease of cytoplasm in the epithelial cells.

Another important characteristic was the development of a nondistinguishable basal layer. This layer seemed to replace the upper layers so that all the cells appeared similar to the basal cells. Of the 15 cases presented 12 cases disclosed this characteristic. The contrast between the basal layer of early carcinoma and normal epithelium can be seen in Case 3 (Fig. 4). In this microscopic section the normal epithelium had a single-cell basal layer; in the carcinomatous zone there was an abrupt change and the basal layer was not distinguishable from the cells above. This characteristic was also present in the areas of metaplasia disclosing changes of early carcinoma. In Case 5 (Fig. 7) the squamous epithelial cells of the entire gland appeared similar and the basal layer was not distinguishable. This change was outstanding in this case as revealed by a comparison with the changes of metaplasia without the characteristics of early carcinoma. In Case 6 (Fig. 8) leucoplakia was

Fig. 2. Case 2. This case discloses several stages of early carcinoma in the same cervix, especially observed in the epithelium in the upper right. Epithelium of lower left is relatively normal $\times 65$.

present in the area associated with early carcinoma. Where leucoplakia was present alone, the basal layer was well defined and several cells in thickness. In the areas of early carcinoma in this section the basal layer appeared indistinguishable from cells above it.

Fig. 3. Case 2. High power photomicrograph of the same case as Figure 2. Basal layer is indistinguishable in the areas of early carcinoma. $\times 395$.

Fig. 4. Case 3. This case reveals the abrupt oblique transition between the early carcinoma and the normal epithelium (lower left of upper strip of epithelium). Other areas of this same cervix reveal invasive carcinoma. $\times 65$.

Mitoses were found occasionally in 10 cases and to a marked degree in 4 cases. In Cases 4 (Fig. 6) and 6 (Fig. 8) may be seen numerous mitotic figures.

The presence of an intact basement membrane was also an important characteristic of early carcinoma and was diagnostic of the pre-invasive stage. In the 6 cases which also contained invasive carcinoma, the basement membrane was penetrated in the areas of invasive carcinoma, even though it was intact in the areas of early carcinoma in the same cervix. In the 9 cases of early carcinoma alone, the basement membrane was intact. Case 8 (no illustration) revealed both conditions in different areas. An intact basement membrane was also seen in the areas of metaplasia associated with early carcinoma as disclosed in Case 5 (Fig. 7).

The line of demarcation between the carcinomatous and the normal epithelium was searched for and was identified in 7 of the 13 cases. In 3 of these the demarcation was sharp and in 4 it was gradual. Case 1 (Fig. 1) disclosed a demarcation on both sides of the area involved. In Case 3 (Fig. 4) the demarcation was very definite and was an oblique

line. In Case 2 (Fig. 2) the transition from normal epithelium to carcinomatous epithelium was gradual. At the upper part of the photomicrograph the cells of the epithelium appeared normal then there was an increase in thickness of the cells of the basal layer. The photomicrographs for Case 7 (no illustration) and Case 8 (no illustration) also revealed gradual transitions.

The stroma underlying the carcinomatous epithelium revealed lymphocytic infiltration in all of the cases presented. This infiltration varied in degree not only in each case but occasionally in different areas of the same case. It appeared that in this series of cases, there was no correlation between the amount of lymphocytic infiltration and the severity of the lesion.

All of the 13 cases also disclosed an increase in the number of cells of the stratum germinativum and of the epithelium as a whole. In the 6 cases of invasive carcinoma, 3 showed a moderate increase and 3 showed a marked increase. In the noninvasive cases, 6 showed a moderate increase, 2 a marked increase and 1 a mild increase. The correlation between the severity of the lesion and the increase of cells was not very definite in this group.

Fig. 5. Case 4. This case discloses the cells described as characteristic of early carcinoma in the still intact epithelium, undistinguishable basal layer and intact basement membrane. No invasion. $\times 100$.

All of the cases also revealed a loss of polarity of the cells. In 4 cases this feature was mild and in 9 cases it was marked. In all of the cases which had invasive carcinoma in other areas of the same cervix, the loss of polarity was marked.

All of the changes previously described were sometimes found in the squamous epithelium which replaced cervical glands as a metaplastic process. Usually the surface epithelium overlying these areas revealed the same changes. Ten cases of metaplasia with changes of early carcinoma in the epithelium of the same cervix were found in the material studied. Three of these cases revealed very little or no carcinomatous changes in the areas of metaplasias. Seven cases (Cases 4, 5, 10, 12, 13, 14, and 15) revealed that the glands with metaplasia were all involved in the changes of early carcinoma. All of these cases showed that the overlying epithelium was also involved in a similar change except in Case 13 where the epithelium was absent due to ulceration. In none of the 7 cases was there an invasion of the basement membrane by the malignant cells in the area of metaplasia. However, 3 of the 7 cases had invasive carcinoma in another area of the same cervix involving the surface squamous epithelium. No

Fig. 7. Case 5. The case discloses metaplasia combined with the morphological changes of carcinoma in the epithelial cells of the metaplastic areas. In the surface epithelium there were also changes of early carcinoma. $\times 100$.

attempt was made to relate metaplasia to development of squamous cell carcinoma of the cervix. The finding of metaplasia may have been only coincidental. However, in 8 cases it participated in the early changes of carcinoma in a manner similar to the participation of the surface squamous epithelium.

There were 2 cases of leucoplakia existing together with the morphological changes of early carcinoma in the squamous epithelial cells. In 1 case the basement membrane was intact throughout the cervix and in the other the basement membrane was invaded in areas. Case 9 showed the invasive carcinoma together with leucoplakia. In this case the areas of early carcinoma with an intact basement membrane in the same cervix revealed the squamous epithelial cells were characteristic of early carcinoma. Case 6 disclosed leucoplakia together with early carcinoma with an intact basement membrane throughout the entire cervix.

Cases 10 and 15 were studied in which only the changes of early carcinoma were seen in several original microscopic sections of the cervix. However, because of the suspicious character of the lesions, further investigation of these cervixes by means of additional sec-

Fig. 6. Case 4. High power photomicrograph of same case as Fig. 5. The undistinguishable basal layer is present at a (Right). $\times 395$.

Fig. 8. Case 6. This case reveals leucoplakia combined with the morphological changes of early carcinoma. Hyperkeratosis and parakeratosis can be seen together. With indistinct probable basal layer are also seen. $\times 100$.

tions from various areas was made and in invasive carcinoma was discovered. This would not have been suspected by the appearance of the cervix from clinical or gross pathological studies and indicates the value of biopsy in the abnormal cervix. In Case 10 the cervix was removed with the uterus with the clinical diagnosis of chronic cervicitis with erosion. In Case 15 the first biopsy revealed evidence suspicious of early carcinoma and the cervix was subsequently removed for further investigation and study.

COMMENT

A series of 15 cases of early carcinoma of the cervix uteri as reviewed 9 of these disclosed no invasive carcinoma elsewhere in the cervix and 6 revealed early invasive carcinoma in the same cervix.

The criteria of early noninvasive carcinoma were interpreted as possessing the following characteristics: (1) The squamous epithelial cells had a decreased amount of cytoplasm with deeply stained, oval nuclei. These changes were found in all of the 15 cases. (2) All cells of the epithelium resembled each other

closely from the basal to the uppermost layer so that the basal layer was not distinguishable. This change was observed in 12 cases. (3) In all cases, there was an increase in the number of cells of the stratum germinativum. (4) In 14 cases mitotic figures were present. (5) The basement membrane was not penetrated in any of the noninvasive cases. (6) The subepithelial tissue in all cases was infiltrated with lymphocytes. (7) Seven of the cases disclosed a line of demarcation between normal and carcinomatous epithelium. In 3 of these the transition was gradual and in the others, the demarcation was abrupt and distinct. (8) All 15 cases showed a loss of polarity of the cells. (9) The changes of early carcinoma were also found in areas of coexistent metaplasia in 8 cases. Usually the epithelium overlying these areas was involved in the same process. (10) In 2 cases leucoplakia existed in conjunction with the changes of early carcinoma in the surface epithelium. In 1 of these 2 cases invasive carcinoma was disclosed in some areas.

Two cases were seen in which the diagnosis of early noninvasive squamous cell carcinoma of the cervix uteri was made, which upon further study because of this diagnosis, disclosed early invasive carcinoma. These examples indicate the value of biopsy and also the value of further investigation of the cervix uteri in cases in which early noninvasive carcinoma has been diagnosed.

As a result of this study the earlier work of Rubin, Meyer, Schiller, Broders, and others is confirmed namely that cellular changes develop in the surface stratified squamous epithelium of the portio vaginalis of the cervix which are regarded as the early manifestations of malignant transformation. That these changes occur before there is invasion and before there is clinical evidence of carcinoma is also demonstrated. The report also indicates that the epithelial cellular changes are similar in noninvasive and early invasive carcinomas in areas not yet frankly or clinically carcinomatous, and closely resemble the changes found in the epithelial cells of frankly or clinically carcinomatous lesions. This tends to support the thesis that the so called intraepithelial preinvasive changes as described are the early

iest signs and the forerunner of carcinoma of the cervix uteri

SUMMARY

A series of 15 cases of early carcinoma of the cervix uteri is presented. These cases reveal changes in the surface squamous epithelial cells which have been interpreted as the early cellular transformations of malignancy in the preclinical preinvasive stage of carcinoma. The changes stand comparison with previous

ly described early invasive squamous cell carcinomas of the cervix and are similar to the changes which are found in clinical frankly invasive squamous cell carcinomas of the cervix uteri. These changes have been described in detail.

ACUTE INJURIES TO THE NECK INVOLVING THE FOOD AND AIR PASSAGES

MANUEL E. LICHTENSTEIN M.S. M.D. F.A.C.S., Chicago, Illinois

INJURIES involving the soft tissues in the neck vary in extent and significance from the trivial, superficial and inconsequential to the most extensive deep disabling life endangering and fatal. The proximity of important structures concerned with the vital functions confined to a small part of the body may account for the small number of patients with severe or serious injuries since it is likely that many die soon after wounding from exsanguination strangulation or aspiration of blood into the bronchial tree. Those who survive the immediate injury are threatened with mediastinitis due to leakage of nonsterile secretions into the retropharyngeal space. This complication is often the cause of death in fatal cases.

Injuries to the soft tissues of the neck in civilian practice occur only occasionally. Stab or gunshot wounds, penetration of glass fragments, and surgical accidents with injury to the trachea, pharynx, or other structures account for some, while injuries due to the swallowing of pins, needles, fish bones, tooth picks, and partial plates account for others.

This report concerns a group of patients who sustained injuries to the food and air passages in the neck, admitted to an evacuation hospital during the Italian campaign. Injuries involving the large vessels of the neck have been reported previously (1). The details of management in this series are presented with the hope that similar reports may help to establish the principles of immediate management of injuries to this part of the body.

CASE 1. Pfc. W., aged 42 years, was injured in a mine explosion at 10:00 p.m. October 17, 1944 and was admitted to the hospital on October 18 at 4:00 p.m. He sustained a penetrating wound of the chin near the midline between the hyoid bone and mental process with lodgment of the missile in the body of the 3rd cervical vertebrae. The missile traversed the pharynx leaving entrance and exit wounds which

opened into the fascial spaces of the neck. An x-ray examination disclosed air in the retropharyngeal space. At 10:00 p.m. October 18, under nitrous oxide-oxygen-ether anesthesia administered by the endotracheal method an incision was made along the anterior border of the upper $\frac{1}{4}$ of the left sternomastoid muscle. Fascial spaces of the neck were exposed and the foreign body was removed from the 3rd cervical vertebra. The contaminating secretions of the pharynx were sponged from the wound and the wound was left open. The posterior wound in the pharynx was exposed but not sutured. Food and water were administered by means of a tube passed through the nose into the stomach from October 18th to 28th. The wound was closed by positioning the head without suture on October 25 and was healed on November 6 at which time he was evacuated to a base hospital for further observation (Fig. 3). Penicillin was given in 25,000 unit doses every 3 hours intramuscularly for 7 days. The entire course was free from complications during the 19 day stay in the hospital.

CASE 2. Sgt. Santos aged 24 years, was wounded by a sniper's bullet at 3:00 a.m. January 9, 1945 and was admitted to the hospital at 4:15 p.m. of the same day. The missile perforated the upper lip on the left side entered the mouth, perforated the tongue, traversed the pharynx, and lodged between the 2nd and 3rd cervical vertebrae. In addition he sustained injuries to the buttocks and extremities. An x-ray examination showed air in the soft tissues of the neck down to the mediastinum. At 9:00 p.m. under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube the fascial spaces of the neck were exposed through an incision along the anterior border of the left sternomastoid muscle. The foreign body was removed and the defect in the posterior wall of the pharynx was demonstrated but not closed. The wound was left open without drains. The wounds of the lip and tongue were debrided and sutured. Feedings were administered for 8 days by means of a tube passed through the nose. Following this he was fed by mouth without difficulty or complaint. By positioning the head and by proper bandaging the wound was closed without suture. The patient was evacuated to a base hospital on January 20. Penicillin was given in 25,000 unit doses every 3 hours intramuscularly. The postoperative course was free from complications and no evidence of infection was noted at any time.

CASE 3. Pfc. L. was wounded by shrapnel at 5:30 p.m. March 2 and he arrived at the hospital 5 hours later. He sustained a penetrating wound of the right carotid triangle with lodgment of a foreign body in

From the Michael Reese Unit (6th Evacuation Hospital, A.U.S.) and The Division of Surgery Northwestern University Medical School.

Fig. 1 Sites of entrance and lodgment of foreign bodies, path of gross tissue damage and location of surgical approach, Cases 1 top, 2, middle, and 3, bottom.

the prevertebral space to the left of the midline at the level of the 4th cervical vertebrae. There were two wounds in the pharynx—a right lateral and posterior. Under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube the retropharyngeal space was exposed through an incision over the right sternomastoid muscle. The foreign body was removed. No closure of the openings in the pharynx was attempted. He was fed for 8 days through a tube passed through the nose. After this he was able to take liquids by mouth. He was given 15,000 units of penicillin every 3 hours intramuscularly. Patient was evacuated to a base hospital on March 14 with the skin wound not yet healed but ready for closure.

These patients (Cases 1, 2 and 3) sustained injuries to the pharynx with leakage of air and pharyngeal secretions into the exposed spaces

in the neck. In the first, the missile lodged in the vertebral body in the second the missile lodged in the intervertebral cartilage, while in the third the missile was free in the retropharyngeal space. In all x ray examinations disclosed free air in the retropharyngeal space—dissecting down toward the mediastinum (Fig. 2). The danger of infection in the spaces of the neck is well known. Decompression of these spaces by incising the fascial wall for the prevention of infection or treatment of established infection is well known and has been successful in the past. The use of penicillin was routine in each case. The freedom from infection in the presence of pharyngeal secretions in the retropharyngeal space would sug-

Fig. 2 Reproductions of lateral views showing air in the retropharyngeal space (Cases 1, 2, and 3).

gest on the basis of experiences in the past that penicillin was a factor in preserving a clean wound in the postoperative period.

CASE 4. P. T. H. sustained a large irregular wound on the right side of the neck between the mastoid process and the angle of the jaw from a mortar shell fragment at 5:00 p.m. January 10 and was admitted to the hospital at 10:30 a.m. of the following day. H. had considerable difficulty in breathing and swallowing. There was a marked bulge in the posterior pharyngeal wall almost occluding the larynx and the mucous membrane was hemorrhagic and swollen. On x-ray examination a large foreign body was disclosed lying anterior to the 1st and 2nd cervical vertebrae projecting beyond the midline (Fig. 5).

A tracheotomy was done under local anesthesia at 12:00 noon and after stabilization of his general condition ether anesthesia was induced through the tracheotomy tube at 5:00 p.m. Provisional control of blood flow in the right carotid artery was provided through an incision along the anterior border of the right sternomastoid muscle. The retropharyngeal

space was exposed and the large foreign body (3 cm. long, 1.5 cm. wide, 1 cm. thick) was withdrawn through the wound of entrance. It was found that no large vessels were injured and the pharynx was not perforated. The wound was cleansed well, damaged tissue was removed and small bleeding vessels were ligated. All wounds were left open. Sulfadiazine in 5 gram doses was given intravenously for 2 days and by mouth for an additional 3 days. The tracheal tube was removed on the 3rd day. Progress was satisfactory and the patient was evacuated to a base hospital on January 18 in good condition.

The large size of the foreign body, the site of penetration and lodgment in the neck, and the small extent of damage found at operation attest to the rôle chance plays in the life of the wounded soldier. The retropharyngeal space was contaminated by the foreign body, but no evidence of infection was ever disclosed.

Fig. 3. Case 4. Method of wound closure effected without suture.

Fig. 4. Sites of injury in Cases 4, top, 5 middle, and 6 bottom, and methods of treatment.

CASE 5 Pvt. R. aged 25 years sustained a shell fragment wound of the neck on October 26 1943 at 12.45 p.m. and was admitted to an evacuation hospital on the same day. While here a tracheotomy was done because of laryngeal injury and a catheter was passed into the esophagus through the débrided external wound on the left side of the neck. He was transferred to another hospital on November 5. His general condition was poor. He had repeated hemorrhages from the neck wound and bled profusely from the mouth. Repeated blood transfusions were given to restore his blood volume. The catheter in the external wound was removed and a tube for feeding was passed through the nose. This decreased the frequency of the hemorrhages but bleeding was still a daily occurrence. On November 12 a Witzel type gastrostomy was done under local anesthesia for

feeding and the intranasal tube was removed. He had no further hemorrhages bleeding ceased from the wound and his general condition improved markedly. He was transferred to a base hospital on November 16 1944 where he continued to improve. He was then evacuated to the Zone of the Interior.

This patient sustained a severe injury in which hemorrhage and infection were the immediate dangers. The cessation of bleeding with removal of the feeding tube passed through the pharynx suggests that pressure and irritation provoked bleeding from granulating surfaces or injured pharyngeal vessels rather than an injury to a large artery or vein.

Fig. 5. Case 4. Note size of foreign body especially its penetration beyond the midline.

The simple gastrostomy, an important measure in this case, provided a means for administering an adequate diet and fluids without disturbing the patient with intravenous or nasal tube feeding. The procedure is valuable and should not be relegated to the position of a final resort in a "hopeless" situation.

CASE 6. Pvt. B, aged 21 years, sustained shell fragment wounds of the neck, chest, and left forearm at 9:00 a.m. January 11 and was admitted to the hospital at 11:30 p.m. of the same day. He coughed frequently with bloody expectoration. There were 2 entrance wounds on the anterior aspect of the neck, little swelling of the neck but pain on pressure over the trachea. X-ray examination disclosed 2 foreign bodies in the midline—one anterior to the cartilage between the 2nd and 3rd cervical vertebrae and the other at the level of the 4th cervical vertebra in contact with the larynx.

Under nitrous oxide-oxygen-ether anesthesia, the wounds were exposed through a collar incision. Damaged laryngeal cartilage was removed and the retropharyngeal space was exposed. One large foreign body with cloth attached was removed.

The patient was fed through a tube for 3 days after which he took liquids by mouth. There was no wound drainage. Sulfadiazine was given in $2\frac{1}{2}$ gram doses intravenously twice daily for 5 days.

He was evacuated to a base hospital on January 17 where wound healing continued satisfactorily.

In other case reports in this series and in another series of vascular injuries of the neck, an incision along the anterior border of the

sternomastoid muscle was used most frequently. In this case a collar incision served to expose the wound tracts and involved spaces. Incisions are made for a purpose and neither the collar incision nor the oblique incision can be regarded as routine practice. In each case a survey is made of the sites of injury structures that must be exposed and the structures that must be available in the wound if one is to prevent needless loss of blood and tissue damage. Collar incisions are preferable but their use is secondary to the requirements of the case. In this instance one small foreign body was not removed but no follow-up examination was possible and the effect of this requires further investigation.

CASE 7. Pvt. K., aged 19 years, sustained shell fragment wounds of the neck, right shoulder, left forearm, and right leg some time before noon June 28, 1944 when he was given first aid and sent to a field hospital at 1:05 p.m. Here because of dyspnea and cyanosis a tracheotomy was done and the patient was evacuated to the hospital at 4:15 p.m. of the same day. On examination the neck presented two large defects with extensive loss of tissue. The entrance wound was about 1 inch in diameter to the left of the midline above the clavicle—the exit wound was 3 inches in diameter on the right side of the neck below the chin. All the intervening tissues had been "blown out." The entire larynx and $\frac{1}{2}$ of the cricoid cartilage were absent and the anterior and lateral walls of the pharynx were missing. Below the hyoid bone there was a large cavity leading in

Fig. 6 Location of injuries in Cases 7, top, 8, middle, and 9, bottom and method of management

feriorly into the trachea and the esophagus. A large portion of the left sternomastoid muscle was missing. The right common carotid artery was exposed in the field. Smaller vessels were thrombosed and the wound was free from hemorrhage. In addition he sustained compound fractures of the left clavicle, right ulna and right tibia. There was an extensive accumulation of nasopharyngeal secretions which were controlled with atropine and mechanical suction. With oxygen therapy and 1,000 cubic centimeters of whole blood his condition improved. Under ether anesthesia administered through the tracheotomy tube the wounds were cleaned, damaged tissues excised and splints applied to the extremities. His general condition was not good. He could not tolerate a feeding tube and was maintained on intravenous proteins, salts, dextrose and vitamins. On July 2 a tubovalvular type gastrostomy was done. He was fed through this and gained considerably in

weight and strength. Because of repeated bouts of aspiration pneumonia, the tracheal orifice was exteriorized. A narrow zone of pharyngeal mucous membrane 1 centimeter wide extended from the nasopharynx to the esophagus. By July 20 he was up and about able to feed himself through the new gastric stoma. He was evacuated on July 24 to a base hospital where the neck wound healed.

This patient sustained a severe injury with extensive loss of substance to the air and food passages of the neck. The gastrostomy in this case was of a type which did not require the presence of a catheter for patency. The valvular effect prevented leakage following filling of the stomach. Exteriorization of the trachea prevented aspiration of nasopharyngeal se-

Fig. 7. Case 7. Loss of larynx, cricoid cartilage and tensor, all of pharynx following passage of missile through the neck. a, On admission with tracheotomy tube. b and c, Following exteriorization of trachea.

Fig. 8. Case 9. Emphysema of soft tissues following tracheal injury.

crections. A narrow strip of posterior pharyngeal wall suggested the possibility of reconstruction of the pharynx by a plastic procedure. However the large cutaneous defect precluded such a procedure at this time.

CASE 8. Sgt. F., aged 24 years, sustained a shell fragment wound of the neck at 3:00 p.m. on May 12, 1945 and arrived at a clearing station at 5:00 p.m. where one unit of plasma was administered. He was evacuated and arrived at the hospital at 7:00 p.m. of the same day. He was dyspneic and coughed with a bloody expectoration. The neck was swollen and emphysematous. A small wound was noted to the

right of the midline below the level of the cricoid. An x-ray examination disclosed a metallic foreign body to the left of the midline anterior to the 7th cervical vertebra with considerable air in the soft tissues of the neck (Fig. 7). Under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube after cannulization of the larynx, a transverse incision was made exposing the tract of the wound. The trachea was perforated. The missile traversed the thyroid gland at the isthmus, passed into and out of the lumen of the trachea, and lodged in the soft tissues to the left of the midline. The damaged thyroid tissue was excised and bleeding vessels were ligated. The openings in the trachea were trimmed, sutured loosely and covered with ad-

adjacent thyroid tissue without tension. The foreign body was removed and the collar incision left open. The patient made satisfactory progress. There was no drainage from the wound and when the patient was evacuated to the base hospital on May 20 the wound was well closed without suture.

This patient illustrated a phenomenon noted in other patients with injuries to the neck. Dyspnea of mild or severe degree is noted frequently especially in vascular injuries but also in any case in which swelling of the neck involving the deep structures develops acutely. It has been found that breathing in the postoperative period is free from difficulty when the fascial spaces are exposed by incision of the tense fascial sheaths.

CASE 9. Sgt W. aged 25 years sustained penetrating grenade fragment wounds of the neck early on June 4, 1944, and was admitted to the hospital at 7:00 p.m. of that day. There was a loss of skin resulting in an irregular defect 4 by 2 centimeters in size at the junction between the chin and the neck on the right side and an irregularly shaped wound 1 centimeter in diameter posterior to the left sternomastoid muscle above the clavicle. The neck was swollen with air in the soft tissues. A cough was associated with a bloody expectoration. An x-ray examination disclosed a foreign body at the level of the anterior surface of the 6th cervical vertebra to the right of the midline and another in the left supraclavicular fossa (Fig. 8). The larynx was swollen and hemorrhagic, the air passage reduced about 50 per cent in size.

Under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube, the wounds in the neck were freed from damaged tissue and the foreign bodies were removed. An exploration of the large vessels, larynx, and trachea was made through an incision along the anterior border of the right sternomastoid muscle and also a supraclavicular incision on the left side. Aside from some small bleeding vessels, only the larynx sustained a perforating wound. The edges of the entrance and exit were excised and the wounds were closed with adjacent tissues. The surgical wounds were sutured. The endotracheal tube was left in place for 1 hour in the postoperative period. Breathing subsequently was unimpaired and the patient progressed satisfactorily. He was evacuated to the base hospital on June 8 in good condition.

In the patients who sustained acute injuries to the respiratory passages immediate closure of the perforation was done at the time initial surgery was undertaken. It is noteworthy that dyspnea frequently present on admission to the hospital was no longer present in the immediate postoperative period and did not

recur. Exposure of the fascial spaces in the neck appeared to be the factor responsible for this freedom from dyspnea.

SUMMARY

1 Injuries to the air and food passages in the neck are not common in patients admitted to an evacuation hospital.

2 Tracheotomy may be necessary and urgently so when signs of obstruction are noted. However in many instances of neck wounds with dyspnea—incision into the fascial spaces as part of the initial surgery of the wound was followed by relief from the signs and symptoms of obstruction.

3 Anesthesia may be administered through the tracheotomy tube or through an endotracheal tube. Aspiration of the trachea and bronchi may be accomplished easily. This is an important factor in the avoidance of pulmonary complications. For wounds of small magnitude local anesthesia is useful.

4 When contamination of the deep neck structures has occurred because of perforation of the oral pharyngeal or esophageal mucous membrane incision into the fascial layers with exposure of the retropharyngeal space prevents edema and spread of infection into the mediastinum.

5 The value of gastrostomy in certain wounds of the pharynx and esophagus should be appreciated and the operation done while the patient is in good condition when tube feeding through the nose is not possible.

6 Tracheal wounds when not too extensive tend to close or may be closed by suture of the overlying fascia muscle, or adjacent thyroid tissue.

7 The skin wounds adjacent to openings in the food and air passages are left open until it is certain the wound is free from gross infection. Closure of the wounds may be done after 5 days by suture or by positioning of the head and purposeful bandaging.

8 Penicillin is used routinely and appears to be a factor in the avoidance of local and spreading infection.

THE TREATMENT OF PANCREATIC PAIN BY SPLANCHNIC NERVE SECTION

GEZA J. TAKATS, M.D., F.A.C.S. and LEROY E. WALTER, M.D. Chicago, Illinois

OF the many causes of abdominal pain the one caused by affections of the pancreas is one of the most severe and most intractable. One can readily distinguish two components. The first is visceral, due to the direct or transmitted stimulation of the celiac ganglion accompanied by girdle pain around the waistline and radiating fanwise to the lower abdomen. This pain is continuous, but shows intermittent lancinating exacerbations not unlike that of a tabetic crisis. Carcinoma of the body of the pancreas, acute pancreatic edema and chronic sclerosing or calcareous pancreatitis all may exhibit such symptoms.

When the lesion extends to the peritoneum the somatic sensory fibers of the lower intercostal or upper lumbar nerves or even the branches of the lumbosacral plexus are irritated. This somatic pain shows skin hyperesthesia in the appropriate segments and sensitivity of the spinous processes of the segmental zones. Muscle rigidity may appear.

Paravertebral block of the corresponding segments extending in the case of the pancreas from the sixth to the tenth dorsal level abolishes visceral pain but only so much of the somatic pain which happens to travel through that area. Mandl in his pioneer monograph on paravertebral injections gave many examples of relieving colics originating in gastroduodenal, gall bladder, renal or other visceral lesions. No mention was made, however, of pancreatic pain. One of us (G. deT.) in a monograph on local anesthesia, advocated the use of diagnostic paravertebral injections for the differentiation of upper abdominal pain.

Intractable pain from the gastrointestinal tract or from the biliary passages has been relieved by paravertebral block with alcohol or by splanchnic nerve section and such in-

stances are on record from the case reports of White and Smithwick who also summarized the previous literature. Craig in 1934, relieved chronic biliary pain by his infradiaphragmatic splanchnicectomy. The pain of gastroduodenal ulceration has been reported to have been relieved by a number of authors even though the aggravation of the ulcer has been suggested by the creation of a relative vagotonia. In the case of Weeks and associates (4b) a painless duodenal perforation occurred in the sympathectomized patient.

The French literature contains an extensive study on the effect of splanchnicectomy in chronic pancreatitis. Mallet Guy and his co-workers reported 11 such cases in which unilateral splanchnic nerve section was done. Of these, all had immediate relief after unilateral (left) splanchnic section but 1 patient showed a recurrence of pain after 5 months, another had only a short follow-up and could not be re-examined. 9 patients had complete relief lasting as long as 2 to 3 years. These patients had all been subjected to exploratory laparotomy and biliary drainage had been unsuccessful in relieving their symptoms. The left splanchnic nerve was sectioned in 10 of the 11 cases below the diaphragm, often with difficulty because of the inflammatory reaction in the retroperitoneal tissues. In 1 case the right splanchnic nerve was cut.

From the same institution Marion reported the treatment with splanchnic anesthesia of 7 patients with acute pancreatitis thus promptly relieving the pain and postponing immediate laparotomy.

In a recent article written by pupils of Leriche (3) 1 case was reported in which splanchnic resection was undertaken for chronic pancreatitis. One case of this sort was also mentioned by Smithwick in a discussion of Whipple's paper on radical surgery for certain cases of calcareous pancreatitis, but to our knowledge it is yet unpublished.

From the Department of Surgery, University of Illinois College of Medicine and the Research and Educational Hospitals. Paper read at the Chicago Surgical Society May 2, 1947.

We wish to report 2 cases in which unilateral splanchnicectomy was performed for intrac table pancreatic pain

CASE 1 CH Hospital No 108768 A 49 year old white male was admitted to the Research and Educational Hospital on December 10 1946 with complaints of pain in the epigastrium radiating posteriorly to the back which had been present for 3 months prior to admission. There had been vomiting shortly after meals for the 10 days prior to admission shortness of breath and constipation of 3 months duration. The pain was described as constant and dull aching starting in the midepigastrium just to the right of the midline and radiating posteriorly to the back in the midline around the level of the lower dorsal vertebrae. There was a weight loss of 15 pounds in 3 months and a marked anorexia. There was no history of clay colored stools or dark urine.

Physical examination revealed a patient of emaciated appearance and chronically ill in appearance. Temperature was 97.0 degrees, pulse 70, respirations 25 and weight was 138 pounds. The heart was normal. There were a few expiratory wheezing rales in the right upper lobe. The abdomen was flat but there was a sense of fullness in the epigastrium although no definite mass was palpated. The upper abdomen in the midepigastrium was moderately tender as were the left hypochondrial and left lumbar areas. Rectal examination was negative. The red blood cell count was 3,730,000 white blood count 9,800. Serum amylase was 146 on December 21 1946 612 on December 30 1946 and 61 on January 11 1947. Total proteins were 7.5 per cent with a serum albumin of 5.5 per cent and a serum globulin of 2.0 per cent. Fasting glucose was 143 milligrams, nonprotein nitrogen .38 and chlorides 511 milligrams per 100 cubic centimeters. An upper gastrointestinal roentgenogram and barium enema were reported as normal. Roentgenogram of the chest revealed a circular density to the left upper lobe considered to be a metastatic lesion. Roentgenogram of the dorsal spine was negative. After adequate preparation for surgery which consisted in part of multiple blood transfusions the patient was operated upon on January 2 1947 by Dr. Warren H. Cole. When the peritoneum was opened a large tumor mass occupying the posterior portion of the pancreas and extending upward to the liver edge was seen. The tumor was estimated to measure 3 by 3 by 5 inches. There were no metastases to the liver although the superior extension of the tumor consisted chiefly of metastatic nodes. In spite of the probable metastasis to the lung resection appeared indicated in view of the patient's extreme pain. However closer inspection of the tumor revealed a superior portion of the mass with its metastatic nodes to completely surround the celiac axis. The hepatic artery could be felt coming out of the center of the mass. This one point, in addition to the complete incurability caused the decision against resection to be made so the abdomen was closed.

In the postoperative period this patient's pain continued and required large doses of narcotics and sedation for effective relief. However even heavy doses of narcotics failed to give him adequate relief. For these reasons consideration was given to the possibility of splanchnic nerve block and perhaps resection of the nerve if indicated by a favorable response to the block. On January 10 1947 a right paravertebral sympathetic block was done from sixth to the tenth dorsal injecting 10 cubic centimeters of 1 per cent novocain at each level. Twenty minutes after the block the patient stated that the epigastric pain had completely disappeared. For 12 hours after the block there was no return of pain. The patient had not received sedation or narcotics for 8 hours preceding the block.

On January 14 1947 under intratracheal anesthesia, Dr. Geza deTakats performed a resection of the right splanchnic nerve from the level of the diaphragm to seventh dorsal. The sympathetic chain was also excised from above ninth dorsal to below the twelfth dorsal. A small tear was made in the pleura during this dissection which was closed with interrupted cotton sutures.

Convalescence from this operation was uneventful and there was prompt relief from the epigastric pain. He was discharged from the hospital on January 23 1947 9 days after the splanchnicectomy. At the time of discharge he was eating well and had gained several pounds in weight. The relief of pain however lasted for only a period of 3 weeks postoperatively. Deep roentgen ray therapy to the pancreas was begun on January 31 1947 and shortly after this the epigastric pain returned. The pain became progressively more severe and again it was necessary to administer narcotics for effective relief. The patient refused rehospitalization and became progressively worse. Death occurred on March 4 1947. Permission for an autopsy was not obtained.

CASE 2 J.A.W. Hospital No 109477 A 22 year old white unmarried female was admitted to the Research and Educational Hospital on December 15 1946 with complaints of extreme constant aching pain in the epigastrium radiating to the left flank. She had been well until December 1945 when she first had noted a dull intermittent pain in the left lumbar area radiating in a radicular fashion to the left hypochondrium. These attacks of pain would occur several times daily and occasionally be associated with vomiting and extreme weakness. She had been hospitalized at another hospital in January 1946 and we were informed that a left heminephrectomy of the lower pole had been performed at this time because of a diagnosis of carbuncle of the kidney. The patient remained in the hospital for a period of 5 weeks. The pain persisted after surgery and 2 weeks following her discharge from the hospital she was readmitted remaining in the hospital until August, 1946. During this period of hospitalization she had had daily chills with temperature elevations to 104 degrees. During the second hospital stay she noted a swelling in the epigastrium there

Fig. 1. Film of the abdomen showing number of calcareous deposits to the left of the spinal column: 1 the level of the first and second lumbar vertebrae. Case 2. Left splanchnic nerv. section and lower dorsal sympathectomy completely relieved the patient's intractable pain.

were intermittent episodes of vomiting, a progressive weakness and weight loss, and a relatively persistent pain in the epigastrium and left lumbar region. After a month of hospitalization the patient was again discharged. Symptoms persisted and in March the patient went on an alcoholic bout because of pain. Severe diarrhea developed after 1 week of drinking and this caused the patient to terminate her alcoholism. She was hospitalized for the third time and a gastrointestinal x-ray series at this time revealed a large mass present posterior to the stomach and displacing this organ anteriorly. This was interpreted as a large pancreatic cyst. The patient was reoperated upon through the old nephrectomy incision, but there were no reported abnormal findings. One week after the operation a roentgenographic study of the gastrointestinal tract revealed a dramatic reduction in size of the cystic mass. After healing of the lumbar incision the patient was discharged from the hospital and stated that she felt somewhat improved although periodic attacks of pain in the epigastrium and left flank continued to occur. For the 24 hours prior to admission to the Research and Educational Hospital the pain had become severe and there had been a voluntary dietary restriction but no vomiting.

On her first admission to this hospital the patient was acutely ill. The temperature was 102 degrees F, respirations 24, and blood pressure 110/60 millimeters of mercury. There was marked dehydration, emaciation and weakness. The heart and lungs were normal. Diaphragmatic excursions were normal. There was a marked distention of the upper abdomen, especially in the epigastrium and this portion of the abdomen was rigid. There was also some rigidity of the lower abdomen but only to a slight degree. The entire upper abdomen was acutely tender. The bowel sounds were active, but not increased. The liver and spleen were not palpable. There was moderate tenderness in the left flank posteriorly. There was no demonstrable fluid wave. Pelvic and rectal examinations were negative. The red blood cell count was 3,800,000 and the white cells were 28,000. The serum amylase was 42 units. On succeeding days the amylase levels were as follows: December 16, 1946, 23; December 21, 38; December 25, 138; December 27, 111; January 4, 947; 69; January 8, 40; January 11, 43; January 14, 50. The remainder of the blood chemistry on the day of admission was: total protein 6.9 per cent with 4.4 per cent serum albumin and 2.5 per cent serum globulin. Nonprotein nitrogen was 35 milligrams glucose was 68 milligrams per 100 cubic centimeters of blood.

A flat plate of the abdomen revealed no free air beneath the diaphragm. There were irregular multiple calcareous densities to the left of the first lumbar vertebra interpreted as pancreatic calculi (Fig. 1). An intravenous pyelogram revealed no abnormalities.

A Levine tube was inserted into the stomach and continuous Wangenstein suction was instituted. Intravenous fluids were administered. Penicillin 50,000 units every 3 hours was begun. Under this conservative treatment there was some slight diminution of the pain during the first 24 hours, but the tenderness and epigastric distention persisted. The white blood count was 28,000 the day of admission and then gradually dropped until the fifth day when it was 4,300. On the third day there was some lessening of the abdominal distention and considerably less tenderness. A diagnosis of pancreatic lithiasis and pancreatitis with possible pancreatic cyst was made and following several blood transfusions and further hydration of the patient an exploratory laparotomy was performed by Dr. Warren H. Cole on December 31, 1946. When the peritoneal cavity was opened a large mass was found pushing the stomach anteriorly in the midline. The gall bladder was normal. The mass consisted of the pancreas, enlarged to three or four times its normal size, nodular and very firm. The fact that it displaced the stomach forward had resulted in an erroneous preoperative impression that it was a cyst. The entire pancreas was involved in the process although the tail was not quite so large. Further exploration of the abdomen was unrevealing, and the wound was closed in layers without drainage. The postoperative

course was uneventful. The pain, however continued and there was severe anorexia with irregular episodes of vomiting which usually occurred after the intake of even small quantities of food. Parenteral fluid therapy was necessary to maintain the patient's nutritional status at all. Parenteral high vitamin therapy and penicillin were continued and in addition a course of streptomycin (1 gram per day) was given for a 10 day period. Considerable sedation was necessary to control pain at all times. There was some slight improvement on the fourteenth day after surgery and at the patient's request she was discharged from the hospital with instructions to return to the out patient department in 1 week for observation. Readmission to the hospital occurred on January 20 1944. The patient stated that since leaving the hospital she had had almost continuous pain nausea vomiting and weight loss so that on admission she weighed only 78 pounds. Her problem remained the same—continuous narcotic administration was necessary to control pain amounting to 3 grains of pantopon a day.

Consideration of splanchnic nerve block or resection was suggested to attempt to relieve this pain and accordingly on January 30 1947 a dorsal sympathetic block was performed. Ten cubic centimeters of 1 per cent novocain were injected paravertebrally on the left side in each of the segments from the sixth to the tenth dorsal. The block was done in the afternoon and in the morning preceding the block no sedation or narcotics had been administered. Within 10 minutes after the paravertebral block the patient reported that there was complete relief of pain and for the first time in many weeks the patient was comfortable. She slept that night without sedation and felt rested. Because of this result resection of the left splanchnic nerve was deemed advisable. On February 4 1947 one of us (G deT) performed a left splanchnic nerve resection including removal of the dorsal sympathetic chain between ninth and twelfth dorsals. This operation was performed under intratracheal anesthesia. The eleventh rib was resected. Reflection of the pleura revealed considerable inflammatory reaction in the posterior mediastinum. The patient tolerated the surgery very well and her postoperative course was uneventful. There was complete relief of the pain in the epigastrium. Abdominal distention disappeared. There was moderate pain over the thoracotomy incision for several days but no sedation was required after the second day. The patient was ambulatory on the second day began to eat a general diet and on discharge from the hospital on February 12 1947 she weighed 82½ pounds. The patient has remained symptom free up to the most recent follow up visit on March 20 1947 and has gained weight steadily. She weighed 107 pounds 2½ months after splanchnic section a gain of 29 pounds.¹

Pain relief in the first case was quite temporary. Because of the extensive spread of car-

Relief of pain persists on re-examination 6 months after operation.

cinoma in the peritoneal and retroperitoneal tissues, this was to be expected. However we were amazed to see the dramatic relief from pain and if confronted with a similar situation one might prefer an alcohol injection to the lower dorsal segments. The return of pain was not due to the presence of the opposite splanchnic nerve since it appeared on the right (operated) side.

In the second case the result so far (6 months at this writing) has been lasting. What struck us most was the sudden disappearance of the epigastric distention and one might speculate whether or not this is a direct effect on pancreatic edema and distention or an interruption of reflex pylorospasm. In this connection one must point to the fact that both cardio-spasm and pylorospasm produced experimentally by vagal section can be abolished by sympathectomy (5) and that pylorospasm in acute biliary and pancreatic episodes is a frequently recognized clinical entity.

The preoperative diagnostic injections of procaine to appropriate segments is advisable here as before any other form of sympathectomy. It is probable that bilateral splanchnic sections may become necessary if the pain should shift to the side not operated upon. However the operation may have a direct effect on the inflammatory process and on the vascularity of the gland thus supplying a direct therapeutic effect (9).

Since the splanchnic nerves are the sensory nerves of the upper abdominal viscera, the question of visceral pain following splanchnic section for hypertension naturally arises (4). Of 250 patients who have undergone splanchnic section done on our service, only a few observations have been made which are germane to this subject. One such patient has been closely studied at our hospital and hence her history is given in detail.

CASE 3. L.S. Hospital No 106791. A 38 year old married woman had a bilateral splanchnic nerve section done on April 30 1946 and on May 21 1946 for a progressive essential hypertension of 13 years duration starting with a pregnancy in 1932. Her average preoperative blood pressure was 213/110 millimeters of mercury and the preoperative work up indicated that she belonged to a group 1 hypertension with little organic damage. She left the hospital with a blood pressure varying from 150 to 126 systolic and 100 to 96 diastolic millimeters of mercury.

She was readmitted to the hospital 3 months later with itching of the skin, jaundice, dark urine, and a mass in the right upper quadrant of 8 weeks' duration. Eight weeks and 6 weeks before admission she had had episodes of nausea and vomiting following heavy meals. After these attacks jaundice and a lump in the abdomen appeared. There was no pain at any time but the nausea persisted. On entrance the patient's blood pressure was 135/95 millimeters of mercury. She was manifestly icteric and the liver was palpable four fingers below the costal margin. Over the edge of the liver a tense, tender gall bladder was palpable. The lesion was so painless that prior to admission a diagnosis of homologous serum jaundice was made since she had received two blood transfusions during each of the splanchnic nerve sections. Of the laboratory findings the urobilinogen and cephalin flocculation tests were negative, blood bilirubin was 15 units, icterus index was 66 and amylase 116 units.

On August 19, 1946 with a preoperative diagnosis of obstructive jaundice Dr. Warren H. Cole found a greatly thickened gall bladder containing stones. There were numerous adhesions between the gall bladder, duodenum and colon. After they were separated a greatly thickened common duct was opened and at least twenty small stones and one large stone about 2.5 centimeters in diameter were removed. The large stone was found to be impacted in a cystic dilatation of the common duct and was wedged in so as to block the duct. The gall bladder was removed and a T tube was placed in the common duct. Convalescence was uneventful. The patient was discharged on the 15th postoperative day and the T tube was removed in 5 weeks.

The percentage of painless jaundice in impacted common duct stones and with a distended gall bladder is not too large but still common enough not to allow a definite statement that the absence of colic here was due to splanchnic section. More important however is the fact elicited after careful questioning that this patient has had upper abdominal distress prior to splanchnic section for 11 years, with occasional bouts of severe pain prior to splanchnic section but never after. Since visceral afferent fibers of the upper abdomen are carried in the splanchnic nerves, the question of eliminating danger signals of threatening perforation may be raised. It must be emphasized that peritoneal irritation is mediated by somatic fibers and that sensation of nausea is known to be mediated through the vagus nerves.

SUMMARY

Two case reports are presented in which unilateral splanchnic nerve section with lower dorsal sympathectomy was done for intractable pain due to pancreatic disease. In the first case the patient was in a terminal phase of an inoperable carcinoma of the body of the pancreas and relief was of short duration. In the second case, that of a chronic recurrent calcareous pancreatitis with exacerbations, the operation resulted in sudden relief now lasting over 3 months in a patient whose pain could not be controlled with heavy doses of narcotics taken over a period of 15 months.

A third case was presented in which a bilateral splanchnic nerve section undertaken for the relief of hypertension was followed by a painless obstructive jaundice for which an impacted common duct stone was responsible.

The value of paravertebral block, followed if necessary by splanchnicectomy, is emphasized in intractable painful upper abdominal pain of visceral origin. This method has not received the attention it deserves.

Since this article was submitted for publication other cases were studied. One patient had a chronic pancreatitis and the second persistent pain following cholecystectomy. Interruption of sympathetic pathways resulted in relief from intractable pain which now lasts for 2 and 3 months, respectively. In the case of Riesenhoff (*J. Am. Med. Ass.*, 94: 34, 30) both splanchnics and both vagi were cut for the relief of pancreatic pain but in our experience unilateral splanchnicectomy and ganglionectomy suffice.

SURGICAL TREATMENT OF IRREDUCIBLE INTUSSUSCEPTION IN INFANTS

J PEYTON BARNES M D F.A.C.S Houston Texas

THE treatment of an intussusception found to be irreducible at operation is the subject of this discussion. The etiology, diagnosis, preoperative and postoperative treatment will not be considered except details which are directly related to the operation.

The incision used is a transverse one slightly below the umbilicus medially and just above the anterior superior spine laterally. One is usually able to retract the right rectus medially enough for adequate exposure but its section does no harm. The peritoneum is also cut transversely. In practically all cases the right lower quadrant is the site of the major work and this incision gives very good exposure of this area.

When it is determined that the intussusception is irreducible, the following steps are carried out:

1. The intussusciens is sutured to the intussusciens, by means of mattress sutures of No. 0 chromic catgut. This step is described in the Jessett operation (Fig. 1).

2. The peritoneum is closed except for a small opening about 3 or 4 centimeters long (Fig. 2).

3. With a continuous suture, the edges of this peritoneal opening are attached to the serous surface of the intussusciens (usually the colon) at a point about 2 inches distal to the placement of the original mattress suture line uniting intussusciens and intussusceptum (Fig. 2). As shown one can place this continuous suture so that the longitudinal band on the colon may be used in the next step. After this third step is completed the operation then becomes strictly extraperitoneal thus the danger of peritonitis is avoided.

4. The wall of the intussusciens is now opened, and the intussusceptum is pulled out and as it is pulled out toward its origin the initial mattress suture line will be felt between thumb and index finger (Fig. 3).

5. When the mattress suture knots are felt the double barreled wall of the intussusceptum is cut through one-half inch distal to the mattress suture line until both edges are clearly defined and a guy suture is placed through both walls (Fig. 4).

6. A continuous suture, running or lock, is started through both these edges, being used to maintain hemostasis as the mesenteric vessels are reached and the cutting across of the intussusceptum is continued (Fig. 4 insert). When the intussusceptum is completely severed and removed the continuous suture is completed and a second guy suture is placed opposite the first. The end-to-end anastomosis has now been completed all gangrenous tissue has been removed and the entire resection has been carried out completely extraperitoneal. The illustration (Fig. 5) shows the details.

7. A small sized catheter about No. 12 or 14 F. which will fit very loosely in the anastomotic opening is passed at least 6 or 8 inches up in the proximal ileum (Fig. 6). The two guy sutures are very helpful in this maneuver. Both guy sutures are removed and the anastomosis is allowed to resume its original position. The final result of this step is shown in Fig. 6 insert.

8. The incision in the intussusciens wall is closed rather loosely and the abdominal incision up to the catheter is also closed loosely about it. A silk stitch anchors the catheter to the skin edges so that it cannot be pulled out. This is important (Fig. 7).

Postoperatively these babies must be immobilized for about 72 hours. The catheter is attached to a continuous suction device as soon as the baby is back in bed and this suction will promptly empty the distended loops of ileum of gas and liquid matter thus allowing peristalsis to be resumed. Since the catheter goes well up in the ileum it serves exactly as an enterostomy and being much smaller in diameter than the anastomotic ring it does

She was readmitted to the hospital 3 months later with itching of the skin, jaundice, dark urine, and a mass in the right upper quadrant of 8 weeks' duration. Eight weeks and 6 weeks before admission she had had episodes of nausea and vomiting following heavy meals. After these attacks, jaundice and a lump in the abdomen appeared. There was no pain at any time but the nausea persisted. On entrance the patient's blood pressure was 125/95 millimeters of mercury. She was manifestly icteric and the liver was palpable four fingers below the costal margin. Over the edge of the liver a tense, tender gall bladder was palpable. The lesion was so painless that prior to admission a diagnosis of homologous serum jaundice was made, since she had received two blood transfusions during each of the splanchnic nerve sections. Of the laboratory findings, the urobilinogen and cephalin flocculation tests were negative, blood bilirubin was 15 units, icterus index was 66 and amylase 116 units.

On August 19, 1946, with a preoperative diagnosis of obstructive jaundice, Dr. Warren H. Cole and I greatly thickened gall bladder containing stones. There were numerous adhesions between the gall bladder, duodenum and colon. After they were separated a greatly thickened common duct was opened and at least twenty small stones and one large stone about 2.5 centimeters in diameter were removed. The large stone was found to be impacted in a cystic dilatation of the common duct and was wedged in so as to block the duct. The gall bladder was removed and a T tube was placed in the common duct. Convalescence was uneventful. The patient was discharged on the 15th postoperative day and the T tube was removed in 5 weeks.

The percentage of painless jaundice in impacted common duct stones and with a distended gall bladder is not too large, but still common enough not to allow a definite statement that the absence of colic here was due to splanchnic section. More important however is the fact elicited after careful questioning that this patient has had upper abdominal distress prior to splanchnic section for 11 years, with occasional bouts of severe pain prior to splanchnic section but never after. Since visceral afferent fibers of the upper abdomen are carried in the splanchnic nerves, the question of eliminating danger signals of threatening perforation may be raised. It must be emphasized that peritoneal irritation is mediated by somatic fibers and that sensation of nausea is known to be mediated through the vagus nerves.

SUMMARY

Two case reports are presented in which unilateral splanchnic nerve section with lower dorsal sympathectomy was done for intractable pain due to pancreatic disease. In the first case the patient was in a terminal phase of an inoperable carcinoma of the body of the pancreas and relief was of short duration. In the second case, that of a chronic recurrent calcareous pancreatitis with exacerbations, the operation resulted in sudden relief now lasting over 3 months in a patient whose pain could not be controlled with heavy doses of narcotics taken over a period of 15 months.

A third case was presented in which a bilateral splanchnic nerve section undertaken for the relief of hypertension was followed by a painless obstructive jaundice for which an impacted common duct stone was responsible.

The value of paravertebral block followed if necessary by splanchnicectomy is emphasized in intractable painful upper abdominal pain of visceral origin. This method has not received the attention it deserves.

Since this article was submitted for publication, other cases were studied. One patient had a chronic pancreatitis and the second permanent pain following cholecystectomy. Interruption of sympathetic pathways resulted in relief from intractable pain which now lasts for 2 and 3 months, respectively. In the case of Roenhoff (*J. Am. Med. Ass.*, 1947, 34: 30) both splanchnics and both vagi were cut for the relief of pancreatic pain, but in our experience unilateral splanchnicectomy and ganglionectomy suffice.

SURGICAL TREATMENT OF IRREDUCIBLE INTUSSUSCEPTION IN INFANTS

J PEYTON BARNES M D , F.A.C.S Houston Texas

THE treatment of an intussusception found to be irreducible at operation is the subject of this discussion. The etiology, diagnosis, preoperative and postoperative treatment will not be considered except details which are directly related to the operation.

The incision used is a transverse one slightly below the umbilicus medially and just above the anterior superior spine laterally. One is usually able to retract the right rectus medially enough for adequate exposure, but its section does no harm. The peritoneum is also cut transversely. In practically all cases the right lower quadrant is the site of the major work and this incision gives very good exposure of this area.

When it is determined that the intussusception is irreducible, the following steps are carried out:

1. The intussusceptum is sutured to the intussusciens, by means of mattress sutures of No. 0 chromic catgut. This step is described in the Jettett operation (Fig. 1).

2. The peritoneum is closed except for a small opening about 3 or 4 centimeters long (Fig. 2).

3. With a continuous suture, the edges of this peritoneal opening are attached to the serous surface of the intussusciens (usually the colon) at a point about 2 inches distal to the placement of the original mattress suture line uniting intussusciens and intussusceptum (Fig. 2). As shown one can place this continuous suture so that the longitudinal band on the colon may be used in the next step. After this third step is completed the operation then becomes strictly extraperitoneal thus the danger of peritonitis is avoided.

4. The wall of the intussusciens is now opened and the intussusceptum is pulled out and as it is pulled out toward its origin the initial mattress suture line will be felt between thumb and index finger (Fig. 3).

5. When the mattress suture knots are felt, the double-barrelled wall of the intussusception is cut through one half inch distal to the mattress suture line until both edges are clearly defined and a guy suture is placed through both walls (Fig. 4).

6. A continuous suture, running or lock is started through both these edges, being used to maintain hemostasis as the mesenteric vessels are reached and the cutting across of the intussusception is continued (Fig. 4, insert). When the intussusceptum is completely severed and removed the continuous suture is completed and a second guy suture is placed opposite the first. The end-to-end anastomosis has now been completed all gangrenous tissue has been removed, and the entire resection has been carried out completely extraperitoneal. The illustration (Fig. 5) shows the details.

7. A small sized catheter about No. 12 or 14 F. which will fit very loosely in the anastomotic opening is passed at least 6 or 8 inches up in the proximal ileum (Fig. 6). The two guy sutures are very helpful in this maneuver. Both guy sutures are removed and the anastomosis is allowed to resume its original position. The final result of this step is shown in Figure 6 insert.

8. The incision in the intussusciens wall is closed rather loosely, and the abdominal incision up to the catheter is also closed loosely about it. A silk stitch anchors the catheter to the skin edges so that it cannot be pulled out. This is important (Fig. 7).

Postoperatively these babies must be immobilized for about 72 hours. The catheter is attached to a continuous suction device as soon as the baby is back in bed, and this suction will promptly empty the distended loops of ileum of gas and liquid matter thus allowing peristalsis to be resumed. Since the catheter goes well up in the ileum it serves exactly as an enterostomy and being much smaller in diameter than the anastomotic ring it does

Fig. 2. Unrolling intussusception from intussusciptum with parallel mattress sutures.

not plug this opening as a tightly fitting tube would. Therefore it serves a double purpose by removing the gas and liquid portions it relieves and prevents distention. It also allows the solid and semisolid matter to pass around

Fig. 3. The peritoneum has been closed with the excision of small opening. The peritoneal edges are being sutured to all of intussusciptum. Dotted line marks site of incision into intussusciptum.

it and to reach the colon. This promotes recovery of normal bowel action.

CASE REPORT

On December 4, 1946, Baby F, white male, aged 13 months, was admitted to St. Joseph's Infirmary to the service of Dr. Byron P. York. The obstruction had been present about 36 hours, and abdominal examination showed a lumpy mass extending from the cecal area all the way up the right side and over across the epigastric area to just a little to the left of the midline. Dr. York made a diagnosis of intussusception.

Fig. 3. The intussusception is pulled out until the mattress suture line is felt between thumb and index finger. The intussusciptum will be sectioned one-half inch distal to this point.

Fig. 4. First gray suture placed through all of intussusciptum and intussusception. Insert, intussusciptum cut half way through, running suture being placed.

Fig. 5. Close-up view after intussusception has been re-moved. Placement of small sized catheter next.

and operation confirmed it. The ileum had run into itself at a point 2 inches proximal to the ileocecal junction and passed through the ileocecal valve up the ascending colon and into the transverse colon. The situation as shown in Figure 1 was present. The operative procedure was performed as illustrated and 18 centimeters of gangrenous ileum were removed. The child made a rapid recovery leaving the hospital on the sixth postoperative day. He was having normal bowel actions per rectum by the third day. There was very little fecal drainage from the colostomy which healed rapidly.

It is of historical interest that in 1905 K. Israel reported 2 cases in which finding an irreducible intussusception he sutured the colon to the peritoneum about as described here opened the colon, resected the intussusceptum and sutured the double edges together to effect an end-to-end anastomosis. These cases were successful and demonstrated clearly the value of the extraperitoneal resection but apparently no attention was paid to his work later. He did not suture the intussusciens to the intussusceptum as shown in Figure 1. This suturing together of the intussusceptum and intussusciens was described by Jessett who also opened the intussusciens and resected the intussusceptum about as shown here. Jessett did not do an extraperitoneal operation and apparently closed the opening in the intussusciens. Both of these two procedures represent very worth while contribu-

Fig. 6. Loosely fitting catheter being passed well up into proximal ileum. Insert, anastomosis allowed to slip back to original position with catheter in ileum.

tions but the procedure described here adds certain safety factors not present in either one.

This procedure may not be applicable in all cases of irreducible intussusception but where it can be used it has certain advantages of great value.

Fig. 7. Abdominal wound closed (more loosely than shown) catheter attached to skin by through-and-through silk suture.

1 It is strictly extraperitoneal after the diagnosis is ascertained and avoids the danger of peritonitis.

2 No tissue is removed that has not already been destroyed by Nature. Thus no additional shock from resection is added.

3 By means of the catheter passed up into the ileum it provides an enterostomy proximal to the anastomosis.

4 The colostomy provides an additional safety valve of great value. The method employed to provide these two safety valves does not interfere with normal bowel function but actually promotes it in every way.

5 By not removing any normal undamaged tissue there is no great loss of body fluids.

6 The operation is easily performed in a short time by an average operator. Since it can be quickly carried out and also since so little of it is actually intra abdominal, there is a minimum of shock present and this is a vital consideration.

SUMMARY

A simple, rapid, mostly extraperitoneal method for the surgical treatment of irreducible intussusception in infants is described.

COLLECTIVE REVIEW

RATIONALE AND FACTORS FOR CONSIDERATION IN COOPER'S LIGAMENT HERNIOPLASTY

CLAUD C. BURTON M.D. DAYTON OHIO

IN the departure from the early operative procedures used in the treatment of inguinal hernia, the significance of certain technical maneuvers may be lost sight of, and when they are revived a half century later they may appear to those unfamiliar with the evolution of hernial operations as new techniques. The late Harvey Cushing said 'No idea is wholly new what is new is getting people to adopt it and act upon it. How true this aphorism is when one attempts to rationalize and present a serviceable conception of myriad technical variants of hernial operations. In such an analysis it is essential that we understand not only the normal but also variations in the normal anatomical pattern which may be present prior to the development and progression of the hernia. Without such knowledge it is not possible to appreciate fully the extent of the parietal deficiency and to evaluate the existing structural distortion which the technical maneuver is intended to overcome. When it is undertaken with this knowledge the repetition of technical pitfalls may be avoided. Further any improvement of a reparative technique has a greater likelihood of success and perhaps of lasting survival if based upon anatomical knowledge fundamental physiological facts, and sound surgical principles. Cumulative knowledge of the relationship and destiny of the parietal strata is being continually enhanced through the diligence of those uniquely equipped to further meticulous anatomical dissection and embryologic research. Cur-

rently Anson and McVay have made notable contributions in this field. Coincidentally correlative clinical application of these anatomical advances has led to a wider adoption of plastic methods in hernial repair.

The universal acceptance of the operative treatment of hernia has now spanned several decades. During this interim of more than a half century there has been increasing surgical experience, which incidentally has afforded the opportunity of introducing many variants in technique without altering the underlying basic principles of the repair. Consequently there have been few milestones in the evolutionary development of modern methods of hernial repair. In surgery as in other fields of endeavor technical procedures, new and old are repeatedly challenged, and perhaps there has been technical quiescence or even temporary regression at times, but the lull in enthusiasm has been short lived. Invariably there has followed a revival of interest which on an extended appraisal resolves any doubt as to the steady improvement in this special field of surgery.

For a quarter of a century one unvarying feature of all hernial repairs was the use of the inguinal ligament as the sheet anchor for the parietal wall. The results of this widely recognized technique, however, were not wholly satisfactory and for this reason a few surgeons (10, 24, 26, 35, 42) proposed the substitution of Cooper's ligament for the inguinal ligament which in reality was not a new idea. Gradually by the process of evolution and revival, Cooper's ligament has become recognized as playing an important auxiliary

THE RELATION OF PROTEIN DEFICIENCY TO EXPERIMENTAL WOUND HEALING

MATHEW W. KOBAK, M.D., EARL P. BENDITT, M.D., ROBERT W. WISSLER, Ph.D. and
C. HAROLD STEFFEE, M.S., Chicago, Illinois

DURING the past three decades the importance of protein metabolism in healing processes has been particularly emphasized (4, 5, 9). However, the manner in which lack of protein affects healing is still a matter of controversy. The present investigations were undertaken therefore to study further the rôle of protein deficiency in wound healing.

METHODS AND MATERIALS

In order to estimate the results a tensile strength apparatus was developed (Fig. 1). By means of slow release of air from a reservoir bottle into an intra-abdominally placed condom it was possible to measure with a manometer the amount of pressure necessary to disrupt wounds of the abdominal wall of rats. This measurement was recorded automatically with a kymograph. After the point of separation had been determined the pressure necessary to expand the condom through the previously disrupted incision was also established. The latter figure was considered the base line and represented the pressure dissipated in expansion of the balloon against the enclosing tissues of the peritoneal cavity and through the wound itself. By subtracting the point of separation from the base line an objective estimate of the tensile strength of the wound could be obtained.

Such a system is essentially a variant of that previously reported by Harvey and Howes. However, the present method tests the maximum strength of the wound whereas in previous devices utilizing air injection the weakest part of the wound allowed escape of the air first. Furthermore, the method of elevating intraperitoneal pressure closely simu-

lates various clinical causes of wound disruption such as sudden diaphragmatic excursion and ileus with distention.

Young adult male albino rats weighing initially from 180 to 220 grams were used. These were divided into 2 groups, one of which was maintained on a low protein ration containing 19 per cent protein ($N \times 6.25$) and the other on a control ration containing 21.1 per cent protein (10). These diets were isocaloric and contained an adequate quantity of vitamins, minerals and fat. Food was offered in weighed quantities daily. The protein depletion period was 3 months.

Ascorbic acid was not included in the diet because it has been found that the rat can synthesize its own complement of this vitamin. However, the ascorbic acid concentration was determined in the plasma of both depleted and control animals. The levels in both groups of animals were found to exceed 1.4 milligrams per cent.

Postoperatively the rats were maintained in individual cages and were offered 20 grams of the respective diets daily. Food consumption was measured postoperatively in 2 groups of 5 animals each for the purpose of ascertaining the caloric intake in the depleted and control animals. This was done because it has been demonstrated (2) that energy intake is a factor which conditions the utilization of protein. It was found that the normal control animals eating practically all of the diet offered had caloric intakes between 1,150 and 1,250 calories per square meter of body surface per day. The smaller protein-depleted animals which were eating slightly less of the low protein isocaloric ration had intakes between 1,350 and 1,850 calories per square meter per day.

Following the period of protein depletion the animals were fasted for approximately 8 hours, weighed and anesthetized by the in-

most parallel rate, the healing in the protein deficient animals lagging by a period of approximately 2 days.

Adjustment of the plasma oncotic pressure by means of gum acacia appeared to have no effect on the tensile strength of the wounds in either depleted or normal animals. Thus, on the fifth postoperative day animals on the low protein regimen alone had wounds which disrupted at an average of 62 millimeters of mercury while the wounds of those on the low protein diet plus intravenous gum acacia separated at an average tension of 65 millimeters of mercury. Animals on the control diet had wounds disrupting at an average tension of 110 millimeters of mercury while the wounds of control animals receiving gum acacia disrupted at an average pressure of 111 millimeters of mercury.

Although differences in weight between the normal controls and the depleted animals might account for the variation in the tensile strength on a given day, it does not seem likely that these weight differences could account for the overall course of the healing pattern as demonstrated in the respective dietary groups (Fig. 2).

In order to control this factor of body size observations were made on a series of young well nourished rats with body weights comparable to the protein depleted animals. In this group as a whole the tensile strength curve showed a consistent rise between the third and fifth postoperative days. On the fifth postoperative day it was found that the tensile strength of the wounds in these smaller animals fell within the range of that of the larger control animals.

Histologic examinations revealed that during the first 2 postoperative days the tensile strength was roughly proportionate to the amount and organization of the fibrin laid down at the line of incision with negligible difference between the protein depleted and control specimens. In addition, there was little evidence of fibroplasia until the third day except in occasional instances in which early activity was present in the normal control preparations. On the third postoperative day definite fibroplasia was observed, with considerable deposition of reticulum. On the

fifth postoperative day (Fig. 3a) it was seen that the fibroblastic number and activity were more pronounced in those animals fed the control ration with collagen formation and only moderate amounts of reticulum. This was in contrast to the protein depleted group (Fig. 3b) in which fibroblastic activity was obviously depressed. In the latter group reticulum was present to a greater extent along the incision and cellular response had neither the organization along lines of stress, the density nor the general maturity noted in the normal animals. Fibroplasia occurred on subsequent days with great intensity in both groups, and collagen formation was particularly pronounced in the normal animals with seemingly only a moderate quantitative cellular difference in the group of animals which were receiving less protein.

Tissue edema was absent and wound infection was not common; however in the protein deficient rats there was evidence of poorer resistance with occasional instances of abscess formation along the suture channels and occasional diffuse leucocytic infiltration. Epithelial healing was characteristically rapid in both groups with regeneration across the plane of incision by the second day after operation.

COMMENT

Further evidence is offered from these experiments that protein deficiency hampers wound healing. The effect of this deficiency has been shown to result in a characteristic delay in healing from the third through the fifth postoperative days.

In general, however within the range of protein depletion with which we worked, it was not possible to correlate serum protein levels or percentage weight loss with wound tensile strengths. Higher or lower degrees of an already well marked protein deficiency did not appear to alter the ability of the tissues to heal. A protein depleted rat which had lost 20 per cent of its body weight exhibited as poor healing as its fellow which had lost 40 per cent of its weight. Likewise rats with serum proteins as low as 3.2 grams per cent produced wounds with as great strength as those in similar animals with serum proteins of 5.0 grams per cent.

It has been claimed by Rhoads, Fleigelman and Panzer that fibroplasia occurs despite the lowered serum proteins. This finding was corroborated in the present studies by the formation of fibroblasts in both the normal and protein deficient animals. However although fibroplasia occurred in animals maintained on the low protein diet, it was marked by a delay in its early phases. Furthermore in acute depletion experiments with maintenance of the oncotic equilibrium it is possible that serum protein levels will not reveal the extent of protein reserves and the ability of the body to regenerate tissue however in chronic protein deficiency a lowered serum protein appears in general to indicate tissue protein loss (8) and in addition impairment of healing.

An interesting question may be raised. Is the delay in wound healing related merely to the presence of a negative nitrogen balance or is the effect due to exhaustion of the protein reserves coupled with the negative nitrogen balance?

In addition to the loss of circulating and tissue protein other associated elements undoubtedly contribute to the disturbed healing. In animals rendered hypoproteinemic by plasmapheresis wound disruption has been shown to occur frequently (9). This result has been attributed to disturbed osmotic relationships and has been prevented by the administration of acacia to maintain oncotic equilibrium (7). The importance of osmotic equilibrium in wound disruption has likewise been emphasized by Koster and Shapiro and they have stressed particularly the importance of the serum albumin fraction in maintaining a normal osmotic system.

Under the conditions of the present study the animals appeared to be in a relatively normal state of fluid equilibrium. They were not grossly edematous. The ratio of carcass water to carcass protein was not significantly disturbed (2). This was true despite the hypoproteinemia and the large tissue loss. It is possible that this was in part due to the relatively high potassium content of the diet (10) with its resultant diuretic action (2). Thus it seems unlikely that edema played any major rôle in the retardation of wound healing observed in these protein deficient animals. The

experiments in which the colloid osmotic pressure of the plasma of the depleted animals was elevated by the injection of gum acacia substantiate this conclusion.

It should be pointed out however that under situations of stress on the fluid regulatory mechanism such as the sudden flooding of the system with excess fluid and salt, edema is much more likely to occur in the hypoproteinemic animals than in the normal. Such edema will undoubtedly add to the difficulties of repair already present in the protein deficient tissues.

SUMMARY AND CONCLUSIONS

1. A method is described for measuring the tensile strength of wounds of the abdominal wall in small animals.

2. The healing of incised wounds of the abdominal wall of rats is delayed in protein deficient animals.

3. With the onset of fibroplasia on the third postoperative day there is in general a marked difference in the tensile strength of the wounds of the animals maintained on the two rations. This difference is most apparent on the fifth day at which time the wounds of the animals on the normal diet are 3 times as strong as those of the animals on the low protein diet. On subsequent days the strength of the wounds rise in parallel fashion those of the low protein group lagging by approximately 2 days.

4. The lowered tensile strength of wounds noted in protein deficient rats during the third to fifth postoperative days is apparently due to (a) diminution in the number of fibroblasts and a decrease in their rate of maturation, and a general failure of the fibroblasts to organize with adequate density along the lines of stress and (b) delay in maturation of the reticulum into mature collagen.

5. No relationship was demonstrated between various concentrations of the lowered blood protein and wound tensile strength nor with respect to the degrees of weight loss and tensile strength. However in the presence of serum protein depletion and marked weight loss, the wounds invariably exhibited a characteristic although moderate delay in the early phases of fibroplasia.

6 Wounds of rats maintained on an adequate protein diet usually heal cleanly by primary intention, whereas those of rats fed a low protein ration tend to heal with more wound infections and excess wound secretions.

PAPILLARY CARCINOMA OF THE THYROID AND LATERAL CERVICAL REGION

So called 'Lateral Aberrant Thyroid'

GEORGE CRILE, Jr M.D. F.A.C.S. Cleveland Ohio

IN 1939 I reported in this journal a series of 13 cases of papillary tumors of lateral aberrant thyroid origin followed for an average period of 4 years after operation. At that time the literature contained no reports of proved distant metastasis from this type of tumor and in none of our cases had distant metastasis occurred. I concluded therefore that these tumors were multiple primary benign or locally malignant lesions arising simultaneously in the thyroid and lateral cervical region as a result of some disturbance in the development of the lateral anlage of the thyroid. It did not seem plausible to believe that the lateral cervical nodules frequently 10 to 20 in number could represent metastasis from a carcinoma of the thyroid and that at the same time all the patients could be cured by simple removal of the thyroid and lateral cervical tumors. In view of the excellent prognosis it seemed more reasonable to consider these tumors as multiple primary relatively benign neoplasms.

Eight years have passed and 9 new cases have been added to the list. All 21 of these patients have been followed for from 5 to 20 years or until their death. The survival record of these patients still lends support to the theory that in some cases at least the lateral cervical nodules are multiple primary tumors of benign behavior. Yet in 1 case we have in controvertible proof of the malignancy of these tumors and of their ability to metastasize distantly and in a second there is strong evidence that this is the case. Similar examples of distant metastasis have been reported by Pemberton (2) Lahey and others since 1939. In view of the continuing controversy

From the Cleveland Clinic.

One has been eliminated because analysis does not indicate with certainty that the nodule was not removed from the thyroid rather than from the lateral cervical region. As this patient had died without recurrence at the time of the previous report it does not materially alter the series.

over the true nature of these lesions and treatment of choice it seems fitting to report the present status of these 21 cases (Table I).

Two patients have died with distant metastases one to the brain (not proved) and one to the axilla and mediastinum (proved by biopsy). One patient died with a local recurrence of the thyroid tumor. Two have died of other causes apparently free from cancer 84 months and 59 months respectively after operation. One patient, who has had only a biopsy is alive and well 20 years with multiple tumors in both lobes of the thyroid and throughout both cervical regions. One patient (previously reported) died after operation (1). The remaining 14 patients are alive and well with no evidence of local recurrence or distant metastasis.

The 3 patients who died as a result of recurrence or metastasis of the tumor died 18 years, 15 years and 9 years respectively after their original operations. Similar cases have been reported by others and hence we must conclude that in dealing with this type of cancer 5 years is no measure of a cure. The thyroid and lateral cervical region of the patient who has persistently refused operation and irradiation for 20 years is filled on each side with nodules ranging in size from 1 to 3 centimeters in diameter. Although the tumors are much more numerous than they were at first, they have never attained such a size as to produce symptoms or a significant visible deformity of the neck. The fact that the number of tumors has increased from 3 to 20 or more suggests metastasis but could be interpreted as the progressive appearance of multiple independent tumors of congenital origin.

One of the 3 patients who have died of carcinoma developed a massive local recurrence 15 years after the original thyroidectomy. Associated with the recurrence was a single lat

eral cervical nodule grossly and histologically identical to the tumors that in the past we have called lateral aberrant thyroids. There was present in this case the rich pedicle of blood vessels so characteristic of the lateral aberrant thyroids and so different from the blood supply of other types of metastases in lymph nodes. Yet metastatic carcinoma histologically identical to that seen in the thyroid and lateral cervical region was later found in the axilla. It is inconceivable that axillary thyroid tissue could be of congenital origin. The patient died $4\frac{1}{2}$ years after the second operation and over 19 years after removal of the original papillary tumor.

The second patient was reoperated upon for a local recurrence of the thyroid tumor 9 years after the original operation and again a single lateral cervical nodule grossly and histologically similar to those described as lateral aberrant thyroids, was found. Six years later (15 years after the original carcinoma of the thyroid was removed) this patient died, apparently with cerebral metastasis, although a postmortem examination was not done.

The third patient developed a large carcinoma of the thyroid which appeared a few months after a lateral cervical nodule was removed. In spite of x ray therapy she died with local recurrence of the tumor 9 years after the original operation.

The remarkable survival record of the other patients with or without surgical removal of the tumors is demonstrated in the table.

The ability of these tumors to metastasize, as shown by the reports of Pemberton (2) Lahey and others and by the progress of our patients since they were reported in 1931 indicates that regardless of their histology and regardless of their relatively benign clinical behavior these tumors must be considered malignant. Yet they must be considered in a separate category of malignancy one in which metastasis is recognized yet cognizance is taken of the usual tendency to grow extremely slowly. They can be characterized as having the following qualities:

1. A marked tendency regardless of histologic criteria of malignancy to metastasize locally to the glands of (a) the lower and mid cervical region behind and about the carotid

sheath (b) the region posterior to the thyroid along the trachea and along the course of the recurrent nerve (c) the superior mediastinum, (d) the posterior triangle of the neck (e) the upper part of the neck in relation to the carotid sheath (f) the midline along the thyroglossal tract, (g) possibly contralaterally although usually a second primary tumor in the other lobe is demonstrable.

2 A slight tendency to metastasize distantly (a) via the blood stream especially to the lungs (b) via the lymphatics to the axilla.

3 A marked tendency for the tumor in the thyroid to calcify scarify or even to ossify the primary tumor often failing to enlarge significantly over a period of many years in spite of the fact that its metastases may show steady growth and increasing numbers.

4 A tendency for the lateral cervical metastases to grow only slowly over a period of many years and to remain encapsulated non-invasive, and freely movable.

A primary tumor has been found in the thyroid gland of every one of 16 consecutive cases in which I have explored the thyroid or removed one of its lobes. Aside from the 4 tumors that we have observed in both lobes of the thyroid all others in the thyroid proper have been single primary tumors. In 3 cases the tumor has infiltrated the gland more or less diffusely forming an adenopapillomatous infiltration of the affected lobe, but in no cases has there been more than one distinct tumor nodule in a lobe of the thyroid. The fact that in the 16 consecutive patients whose thyroids I have explored there have been multiple lateral cervical nodules and only one nodule in the lobe of the thyroid would seem an argument against the hypothesis that the tumor in the thyroid is, as some believe a metastasis from a primary malignancy in the lateral cervical region. These observations tend to substantiate Pemberton's theory that most, if not all, of the lateral cervical nodules are metastases of a carcinoma primary in the thyroid.

Against this view we have 5 patients followed for from 5 to 14 years after removal of a lateral cervical nodule who have never developed any palpable tumor in the thyroid. That this does not rule out the presence of a primary tumor in the thyroid is illustrated by an

additional case in which 6 years intervened between the removal of a lateral cervical nodule and a second operation for recurrent lateral cervical nodules. Prior to the second operation no tumor was palpable in the thyroid yet at the time of the second operation a tumor 1.5 centimeters in diameter was found in the lobe on the affected side. The tumor was surrounded by much dense scar tissue. It is quite likely therefore that many of the primary tumors in the thyroid enlarge little at all over a period of many years and so may escape detection unless they are searched for. Yet these same tumors may as in this case continue to give rise to actively growing metastases while the primary tumor fails to enlarge.

Experience has shown that even a partial lobectomy does not rule out the presence of a small primary tumor. I have recently removed a papillary carcinoma of the thyroid and a number of lateral cervical nodules a little over a year after a "thyroidectomy" had been performed. At the time of the first operation neither the surgeon nor the pathologist was aware of the presence of this tumor which as is so often the case lay on the posteromedial aspect of the thyroid an area avoided by many surgeons. On another occasion before I became aware of the significance of the lateral cervical nodules in respect to the thyroid tumor I explored the thyroid of a girl with lateral cervical nodules and reported it normal only to reoperate for recurrent cervical nodules a year later and find that there was indeed a tiny nodule less than 1 centimeter in diameter on the posteromedial aspect of the thyroid. Thus failure to demonstrate a tumor in the thyroid at operation or in the portion of the gland removed does not by any means rule out the possibility that a tumor in the posteromedial remnants was overlooked.

The extreme slowness of growth of certain of the tumors in the thyroid is illustrated by the case of a girl 20 years old whose thyroid contained a nodule estimated to be 1.5 centimeters in diameter. Lateral cervical nodules were removed but the thyroid tumor was not disturbed. Fifteen years later more lateral cervical nodules and the thyroid tumor were removed but after all these years the tumor

and in some instances, fundamental, role in her nioplasty. The employment of this ligament augments the security of the floor and presents points of surgical excellence not possessed by transfixion of the wall to the inguinal ligament.

Many technical variants in the practical application of Cooper's ligament have been described but the criteria for the use of this ligament as contrasted with the inguinal ligament have not been presented in the literature. Several factors may be responsible for this missing link in the progressive use of Cooper's ligament for repair. A discussion of some of these factors is the purpose of this paper. It will be confined to (1) the evaluation and availability of Cooper's ligament, (2) reasons for lack of more general acceptance of hernioplasty with Cooper's ligament, and (3) the proposal of criteria for its employment. A description of our technique and a statistical analysis of our results are in preparation.

COOPER'S LIGAMENT

Of the surgically important ligaments of the inguinal region, the iliopectineal (Cooper's) is perhaps the least known generally yet, in 1804 it was described by Sir Astley Cooper who was the first to propose its use in the repair of femoral hernia. However the clinical application of Cooper's proposal was not realized until 1876 when Annandale employed this ligament in the closure of the femoral ring following ligation of the femoralized sac. This operation antedated by 11 years the publication of Bassini's classical and world renowned technique for the repair of inguinal hernia with Poupart's ligament. To Lothelissen (1898) and to his contemporary Narath, are given the distinction of being the first to use Cooper's ligament in the repair of inguinal hernia. Incidentally Lothelissen was operating on a recurrent inguinal hernia when he discovered that Poupart's ligament was totally inadequate and did not exist as an integral structure. Consequently out of dire necessity and drawing on his fund of anatomical knowledge he exposed Cooper's ligament to which he transfixed the conjoined tendon. Despite Lothelissen's resourcefulness and his success in 12 repairs, there followed a long interim in which the use of this ligament was abandoned. Its use was subsequently revived by Moenchowitz, Scelig and Tuholake, Dickson, McClure and Fallis, and others (18, 32-35). In striking contrast, during the same period there was remarkable progress made in the treatment of indirect and direct hernias by employment of the inguinal ligament with disregard of the potentialities of the underlying deeper ligamentous structure. This con-

ing revolutionary concept in the development of hernial operations, with the use of Cooper's instead of Poupart's ligament, was brought about by the introduction of the Bassini-Halsted technique which was given wide publicity in the medical journals of the Continent and America. The simplicity of the latter and the feature of repositioning the cord gained rapid acceptance which has survived perennial challenges for a half century.

The fascial composition of Cooper's ligament has been variously described. Authorities, however are generally agreed that no fascia is basic in its formation but represents fusion of adjacent closely anatomically and generically related fascial and aponeurotic planes, the fascia transversalis, the lateral expansion of the rectus insertion, and the pectineus fascia. Cooper's ligament is pyriform, remarkably constant, and of unvarying density. It is adherent to the superior pubic ramus and intimately attached to the iliopectineal line. It has an internal or vertical surface and a dense superior almost flat surface. The underlying pecten of the ramus is ridge-like which produces the overlying angulation of the ligament at the juncture of its vertical and superior surfaces. Some French and German anatomists have enumerated in minute detail the fascial, tendinous, and aponeurotic structures that conjoin to form Cooper's ligament, but which actually are of little practical surgical importance. A review of the current literature strikingly illustrates that former obstacles to the use of Cooper's ligament are being overcome and the acceptance of this type of hernioplasty as one of the standard techniques is decidedly on the increase. In the broader concept there is no dissent regarding the gross anatomical demarcations or structural sufficiency of this ligament. Further it possesses certain strategic advantages not inherent in the inguinal ligament. Its boundaries do not become distorted by the herniated mass; there is no alteration in its topographic classification, and it does not become attenuated or fragmented. This ligament is not so easily accessible as the inguinal ligament and confusion persists in regard to its terminology.

REASONS FOR RELUCTANCE IN ACCEPTING COOPER'S LIGAMENT IN HERNIA REPAIR

Tardiness of the profession in general in accepting the use of Cooper's ligament in hernia repair may be attributed to the following reasons:

1. The decided lack of accurate and detailed knowledge or available textbook references to this ligament. This deficiency in knowledge of the aponeurotic and fascial continuities encountered

in the thyroid was only 2 centimeters in diameter. The fact that no tumor appears in the thyroid even 10 or 15 years after removal of lateral cervical nodules does not therefore prove that there is no primary tumor in the thyroid. It means only that in all probability the tumor in the thyroid is very small, lies deep on the posterior surface of the gland and is either growing very slowly or its growth is prevented by calcification and scarring.

One of the most significant features of these tumors is the fact that in every one of the 16 patients with lateral cervical nodules whom I have explored I have found a tumor in one or both lobes of the thyroid. The fact that in 5 cases tumors were found in both lobes of the thyroid suggests that the thyroid tumors originate in some congenital rest or anomaly of development. The youth of the patients (6 had developed lateral cervical nodules by the age of 20) also suggests a congenital origin, as does the histologic appearance of some of the cervical nodules. Yet in other cases the lateral cervical nodules are clearly metastases in lymph nodes and it is therefore reasonable to assume that most if not all of the lateral cervical nodules are metastases from the thyroid.

Regardless of the origin of these tumors or of their classification in respect to malignancy, their treatment should be surgical excision. It is indeed a strange type of cancer that can be controlled for 15 or 20 years by local excision of the primary tumor and individual removal of 15 or 20 or more metastatic nodules. It is also a curious type of malignancy which without any form of treatment grows so slowly that in over 20 years the nodules have not enlarged appreciably and have merely become more numerous. It is almost as if these tumors were metastasizing congenital rests having little or no energy of growth. Yet in other cases the tumors enlarge fairly rapidly and sometime attain considerable size. When the primary tumor of the thyroid rather than the lateral cervical nodules is noticed first, the growth energy appears to be greater. Three of the 4 patients who eventually died as a result of tumor developed a bulky tumor of the thyroid as the initial symptom. There were only 2 other patients in the entire group whose thyroid tumors were noticed before the lateral

cervical nodules. The patients whose initial symptoms are referable to bulky tumors of the thyroid and in whom lateral cervical nodules are late developments should perhaps be placed in a different category from those in whom the lateral cervical nodules are the initial and most striking manifestations of the disease.

Complete removal of the tumors involving the posteromedial aspect of the thyroid and of the metastatic nodules along the trachea and the course of the recurrent nerve is often very difficult. The scarring and calcification of the tumors in this location render them adherent and often make it difficult to identify, isolate and preserve the recurrent nerve. If a meticulous dissection of the nerve is made however it is usually possible to preserve it. Often it is necessary to isolate and dissect out the entire cervical portion of the nerve. Even when it is adherent to the tumor it may be possible to separate it from the mass without either leaving tumor tissue or damaging the nerve. On several occasions it was impossible to save the nerve without leaving tumor tissue and hence after dissecting it out it was necessary to sacrifice it. When the choice lies between sacrifice of the nerve and removal of all tumor the nerve should be sacrificed.

It is apparent from the table that most of the patients in this series have had more than one operation and that some have had three. All of the patients who have had three operations were operated upon early in our experience before we were aware of the fact that a tumor is usually if not always present in the thyroid. Metastasis therefore continued to occur from the thyroid tumor until it was removed.

Even after the importance of the thyroid tumor was recognized many of the patients with 15 or more lateral cervical nodules required a second operation for removal of one or more overlooked nodules. In several instances the recurrence was contralateral or mediastinal and in one it was in the thyroglossal tract. In only 1 case was the recurrence in the field of the first operation and only in this case would a block dissection of the neck have eradicated the tumor more completely than mere removal of the nodules.

In most of the patients the recurrences were first noticed within a few months of the first operation, and most of these patients were operated upon promptly and have remained well for from 5 to 10 years. In 2 instances the recurrences were noted early but operation was deferred as the result of the war for 4 or 5 years. The nodules enlarged only very slowly and no more nodules developed, again suggesting that if the source of the trouble in the thyroid is eradicated the tendency for additional lateral cervical nodules to develop is controlled.

CASES ILLUSTRATING SLOWNESS OF GROWTH

A patient was seen in 1925 complaining of lumps in the neck of 6 years' duration, first noticed at the age of 16. Several large soft glands were palpable in the left lateral cervical region. A diagnosis of tuberculous adenitis was made. Three x-ray treatments (2 with 30 per cent erythema dose and 1 with 50 per cent) were given without benefit. A biopsy was reported as revealing metastases of a papillary carcinoma of the thyroid. An aberrant papillary adenoma of the thyroid. The patient refused further treatment. In 1939, 14 years later the patient had a hard tumor 2.5 centimeters in diameter in the left lobe of the thyroid, a hard tumor 1 centimeter in diameter in the midline above the isthmus, as well as a tiny hard nodule in the right lobe of the thyroid and numerous lateral cervical nodules beneath the sternomastoid on each side. None of these nodules was large enough to be visible except the one above the isthmus. In 1946, 2 years after biopsy and 27 years after the nodules had first been noticed the patient writes that she has no symptoms referable to the tumors and has only one small tumor in the front of her throat.

A woman, aged 21, first noted glands in the right side of her neck a year before entry. There was a large round fluctuant cystic mass 6 centimeters in diameter at the base of the neck on the right under the sternomastoid. There was a firm nodule 3 centimeters in diameter in the superior pole of the right lobe of the thyroid and two firm round masses 2 centimeters in diameter under the sternomastoid on the right. A diagnosis of tuberculous adenitis or branchial cyst was made. Eleven light x-ray treatments were given without improvement. Four of the lateral cervical masses were removed and the pathologist reported multiple cervical papilliferous cysts of the lateral aberrant thyroid. The thyroid was not explored. The patient returned 14 years after operation and more than 16 years from the time the tumor was first noticed. She had no symptoms referable to the cervical tumors, but examination revealed a hard nodule 3 centimeters in diameter at the right lobe of the thyroid and bilateral cervical nodules. The left lobe of the thyroid seemed normal.

At operation there was a partly calcified papillary carcinoma of the right lobe of the thyroid gland 3 centimeters in diameter and a similar tumor 1 centimeter in diameter in the left lobe. There were 8 lateral cervical nodules, some present on each side in the neighborhood of the thyroid as well as posterior to the carotid sheath and in the superior mediastinum. Convalescence was uneventful and 3 months later there was no evidence of recurrence. This case is interesting because it shows how long these tumors can be present in the thyroid without enlarging appreciably or causing symptoms other than those referable to the lateral cervical metastases. It also indicates that as was the case in the left lobe a tumor may be present without being palpable prior to operation.

CASES SHOWING THAT METASTATIC NODULES MAY CONTINUE TO DEVELOP UNTIL THE PRIMARY TUMOR IN THE THYROID IS REMOVED

A girl, aged 18, had noticed lumps in the right lateral cervical region for 3 years. Later similar lumps developed on the left side and enlarged steadily. A biopsy of one of the lumps was reported as metastatic adenocarcinoma. Twenty-one x-ray treatments with a total of 4000 r units were given, and the nodules decreased slightly in size for a few weeks and then began to enlarge again. Examination revealed nodules 3 centimeters in diameter beneath the sternomastoid on each side, but no abnormality of the thyroid was noted. Through a thyroidectomy incision Dr. George Crile, Sr. removed 5 cystic nodules from the region of the carotid sheath on each side. One of the tumors was removed from the mediastinum at the level of the arch of the aorta. The thyroid was examined and reported as normal. The pathologist reported the tumors as multiple benign intracystic papillomas of lateral aberrant thyroid origin.

Six months later the patient noticed a recurrent tumor in the right lateral cervical region. Examination showed several small firm nodules behind the lower part of the sternomastoid on the right and an enlargement of the left lobe of the thyroid. At operation a tumor 3 centimeters in diameter was removed from the region of the carotid sheath on the right. The left lobe of the thyroid containing a tumor 1 centimeter in diameter also was removed. The right lobe of the thyroid was examined and found to be normal. The pathologist reported a small localized papillary adenomatous growth in the left lobe of the thyroid. It was thought that this tumor and the lateral cervical nodule, which was of similar histology, were both benign.

The patient remained well for 3 years and then developed a small firm nodule in the right lobe of the thyroid 1 centimeter in diameter. At operation the right lobe of the thyroid containing a small tumor was removed and 9 separate nodules were removed from the lateral cervical region and superior medi-

astinum. The pathologist again reported papillary adenomas of the thyroid and of lateral aberrant thyroid origin.

It is over 6 years since the last operation and the patient has had no further recurrences. It was not until the 2 primary tumors in the thyroid were resected that the lateral cervical nodules stopped forming.

A woman, aged 39, had developed a lump in the right side of her neck 5 years before entry. In 1932 Sir John Fraser had removed aberrant thyroid tissue from the right side of her neck at the Royal Infirmary, Edinburgh, Scotland. Shortly after operation the lump reappeared. It was again removed in 1936.

Examination showed a nodule 2.5 centimeters in diameter beneath the lower part of the sternomastoid on the right. The thyroid was normal.

In 1937 Dr. George Crile Sr. removed a nodule from the region of the carotid sheath low on the right. It was reported as a cystic papillary adenoma of lateral aberrant thyroid.

A month later another tumor was noticed in the same location and 5 months later 3 papillary adenomas were removed from the same region. A month later there were no masses palpable in the lateral cervical region but a tiny nodule could be felt in the thyroid gland. The patient returned to England but her sister informs us that the patient has had several more nodules removed from her neck. It is now 15 years since the onset. I do not doubt that she will continue to form nodules until the primary tumor in the thyroid is removed.

CASES ILLUSTRATING GOOD PROGNOSIS IN SPITE OF EXTENSIVE METASTASIS

The following cases in which there were 20 or more lateral cervical nodules illustrate the excellent prognosis (at least for the first 5 or 10 years) which may follow surgical removal of the primary tumor in the thyroid and lateral cervical nodules, regardless of their number and distribution.

A boy was first seen at the age of 10 at which time he had a soft diffuse enlargement of the thyroid which was treated as an adolescent goiter by administration of iodine. The thyroid was examined repeatedly for the next 9 years and no abnormality of the thyroid other than a slight diffuse enlargement of the entire gland was noted.

At the age of 19 he developed nodules in both lateral cervical regions from the angle of the jaw to the clavicle and a hard nodule the size of a pea in the right lobe of the thyroid. A diagnosis of carcinoma of the thyroid with metastasis was made and through anterior sternomastoid incisions dissections of the neck were performed without removal of either jugular vein or sternomastoid muscle. There were tu-

mors in both lobes of the thyroid. All of the right lobe and almost all of the left lobe were removed. Numerous lateral cervical nodules estimated at over 20 on each side were removed from the region posterior to the thyroid from the superior mediastinum and from along the entire length of the carotid sheath. One month later 2 nodules were noted beneath the angle of the jaw on the right at the upper aspect of the previous operation. These were removed. The pathologist reported papillary carcinoma of both lobes of the thyroid with bilateral metastasis to the cervical glands. The tissue was very cellular having some tendency to form glands, papillomatous growths, and large solid masses of closely packed cells. The patient has remained well and free of recurrence for over 6 years and x-ray examination of the chest shows no abnormalities.

Three other patients with extensive thyroid and lateral cervical involvement by carcinoma each of whom had 25 or more lateral cervical nodules and one of whom had a frank malignancy with invasion of veins by the tumor are well from 8 to 10 years following operation. These are Cases 1, 2, and 4 reported previously in this journal (2, 3).

It is clear therefore that the prognosis in these cases is not entirely dependent either on the histologic appearance of the tumor nor on the extent of the lateral cervical metastasis. The 4 patients who have died as the result of papillary tumors of the thyroid with lateral cervical nodules all had tumors which were originally reported as benign from a histologic standpoint, and in 3 of the 4 cases metastasis to the lateral cervical region did not appear for many years. It is urged, therefore, that regardless of the extent of the lateral cervical metastasis and regardless of the apparent malignancy of the lesion papillary tumors in the thyroid lateral cervical region and mediastinum should be removed surgically. Since none of the 3 patients in this series who had adequate x-ray treatment showed either primary regression or permanent control of the tumor x-ray cannot always be relied upon to control this type of cancer. We have reserved its use for those cases in which surgery has failed.

SUMMARY

1. Twenty-one cases of papillary carcinoma of the thyroid and lateral cervical region are reported.
2. All patients have been followed from 5 to 21 years or until their death, and only 3 have

died from cancer 1 with local recurrence in the thyroid and 2 with distant metastases.

3 The patients who died of cancer lived for 9, 15, and 19 years, respectively after the original thyroidectomy.

4 One patient who has refused all treatment is living and well 27 years after the appearance of lateral cervical nodules and 21 years after these nodules were proved to be papillary tumors of the thyroid.

5 In judging the results of treatment of papillary carcinoma of the thyroid the usual 5 year period is meaningless. Twenty or more years may be required before one can be sure that the patient is cured.

6 In 16 consecutive cases with papillary tumors of the lateral cervical region, when the thyroid was carefully examined, a primary tumor in the thyroid was found.

7 It is thought that the lateral cervical nodules are probably metastases from a tumor of the thyroid rather than, as I previously believed, primary tumors of congenital origin.

8. Lateral cervical tumors may continue to form until the primary tumor in the thyroid is removed. Following this no more lateral cervical nodules appear.

9. In the few cases in which x ray has been given the results have been disappointing.

10. The results of excision of the primary tumor and the lateral cervical and mediastinal metastases have been excellent. Four patients who had 20 or more lateral cervical and mediastinal nodules are well and free of re-

currence for from 6 to 10 years after operation.

11 The lateral cervical nodules rarely invade muscles or blood vessels and block dissection of the neck is therefore not necessary. Since most of the patients are young women, whose necks one would hesitate to mutilate needlessly by a block dissection, it is an advantage to perform the operation through a thyroidectomy incision or in the more extensive cases through an incision parallel to the sternomastoid.

12 The tumor in the thyroid may be very small and often is not palpable before operation. On several occasions it was not found until the gland was rotated up out of its bed to expose the posteromedial surface.

13 The tumor in the thyroid usually is scarred or calcified and may not enlarge appreciably over a period of many years in spite of the fact that it continues to give rise to lateral cervical metastases.

14. Regardless of the histology of the tumors and regardless of their apparent hopelessness as suggested by the extent of metastasis, the primary tumor in the thyroid and the lateral cervical and mediastinal metastases should be excised.

COMMON AND UNCOMMON PATHWAYS IN THE SPREAD OF TUMORS AND INFECTIONS

ERNEST LACHMAN M D Oklahoma City Oklahoma

THE rationale of surgical intervention in the spread of tumors and infections is by necessity based on a knowledge of the pathways for the propagation of these noxious agents. This is where the anatomist enters the field. It is his function in co-operation with the pathologist to map out the channels along which the spread takes place. As different as their pathology is the avenues along which cancers and infections travel, are essentially the same, namely the blood and lymph channels. This is the reason why the two disease entities have been combined in the title of this paper. It is certain that we have here a very fruitful field for anatomical research and that many of the peculiarities of metastatic distribution can be explained only on the basis of circulatory anatomy. Selected chapters in the field of cancerous and infectious spread will serve to illustrate the relevant points.

EMISSARY VEINS AS PATHWAYS OF INFECTIONS

Among the pathways of infections, that have become of interest lately are the veins that connect the venous system outside the skull with the venous sinuses on the inside. There is a rich venous network in the face, the infratemporal region and around the pharynx which in some places assumes the configuration of venous plexuses such as the pharyngeal and pterygoid plexuses. These extracranial veins anastomose through foramina of the skull with the large venous channels that are formed by the dura, the dural venous sinuses. What is the function of these connecting or emissary veins as they have been called? They act as safety valves in case of increased intracranial pressure. The connection of the internal jugular vein which drains these venous sinuses, with the right heart is close enough so that pressure

changes in the thorax due to coughing sneezing straining muscular exertion, and forced expiration are readily transmitted to the internal jugular vein and through it to the dural sinuses. This would lead to an abnormal increase in intracranial pressure if it were not for the emissary veins acting as safety valves. We have to visualize in these veins a to and fro movement of the blood, the direction of which depends on the changing pressure conditions in the internal jugular vein. The sinuses and most of the facial veins are devoid of valves a factor which facilitates the reversal of the blood stream.

On the other hand the tortuosity of the lateral sinus and of the beginnings of the internal jugular vein as well as the meshwork of septa in some of the sinuses act as a check mechanism preventing too much suction on the sinuses in case of a rise in negative pressure in the large intrathoracic veins. These same factors are also responsible for a slowing of the blood flow in the sinuses which might account for the frequent occurrence of aseptic sinus thrombosis. But more dangerous than the sterile type is the septic thrombosis of the sinuses which is transmitted to them by way of the emissary veins. We know how readily infection of the lips and nasal area may lead to cavernous sinus thrombosis which before the advent of chemotherapy was almost invariably fatal. It is the easy reversibility of the venous blood flow in the absence of valves and the milking motion of the ever contracting muscles of facial expression around the veins that are responsible for the dislodgment of a septic thrombus and its passage into the dural sinus. Or an infectious thrombophlebitis in the labial veins may spread by continuity into the angular and ophthalmic veins and from there into the cavernous sinus leading to sinus thrombosis and meningitis or generalized sepsis. Infection of the orbit and of the frontal and ethmoidal paranasal sinuses

may travel the same path. Peritonallar infection may cause thrombophlebitis of the pharyngeal plexus and spread from there by way of emissary veins through foramina in the base of the skull likewise to the cavernous sinus. Erysipelas of the scalp may infect the superior longitudinal sinus through the parietal emissary vein. Most common is the involvement of the sigmoid sinus in mastoid infection which may spread to the sinus by way of a thrombophlebitis of the middle ear veins, by way of the lymphatics or by continuity directly from the infected mastoid bone (Braun). The emissary veins are also responsible for the fact that spread of infection from the dural sinuses into the general circulation cannot be prevented with certainty by ligation of the internal jugular vein, since the infection may pass the ligated vein by way of emissary veins in the region of the occiput which communicate with veins of the neck.

Attention has been called to an otitic hydrocephalus, complicating middle ear infection (Symonds, 1937). The condition characterized by bilateral papilledema and severe headaches, results from an increase in intracranial pressure which is brought about by an infection of the sigmoid sinus and by spread of this infection to the superior longitudinal sinus. It is not so much the thrombosis of this sinus, but rather the thrombophlebitis, i.e. the infection of the sinus, which interferes with the absorption of the spinal fluid through the arachnoid villi and leads to rise in intracranial pressure (Symonds, 1937). Symonds (1940) showed that infection in the neighborhood of the tonsils and in the nasopharynx may also lead to hydrocephalus by secondary involvement of the superior sagittal sinus. Thrombophlebitis of this sinus may then spread in retrograde direction into the superior cerebral veins which drain into this sinus and which supply the motor area of the brain. The results are cortical symptoms such as focal epilepsy and hemiplegia. Lately Martin has described a combination of increased intracranial pressure and focal signs of cortical involvement such as convulsions and hemiplegia occurring in the first weeks of the puerperium. The disease may lead to recovery or death. The interesting point is that these so-called

thromboses of the venous sinuses and cerebral veins are actually emboli that by a devious pathway have been transported to the brain from pelvic veins, by passing lungs and other organs. This newly described avenue will be dealt with in later parts of this paper. Here it may suffice to point out that there is an important anastomosis between the veins of the vertebral canal and the dural sinuses through the great occipital foramen.

LYMPHATIC SPREAD OF CANCER OF THE BREAST

Having presented a location which exemplifies the venous spread of infection it may be appropriate to turn to another mode of propagation namely the lymphatic pathway and select a malignancy for illustration. An ideal representative is cancer of the breast, because it is so easily accessible to surgery and anatomical study. It was this location of cancer for which Sampson Handley developed his theory that cancer spreads centrifugally in all directions from its point of origin by permeation i.e. continuous invasion of lymphatic plexuses. While Handley's theory of continuous lymphatic spread to distant points in the organism is too dogmatic and narrow since it disregards lymphatic embolism and venous propagation of cancers, it nevertheless placed the operative treatment of cancer on a rational, i.e. anatomical basis. It laid the scientific foundation for the radical surgical treatment of cancer of the breast which had been developed previously by Halsted on an empirical basis. Halsted's operation exemplified the fact that cancer can be cured even after it has spread from its primary focus to the regional lymph nodes, an experience which is borne out in other locations.

Since the pathways of metastatic spread of mammary cancer were discussed in detail in a previous paper (Lachman) only those facts shall be pointed out here that can be applied also to other areas where lymphatics are involved in the propagation of tumors. The principal lymphatic drainage of the breast passes from its subareolar plexus to the pectoral, central, and apical nodes of the axilla, and from there with or without interposition of supraclavicular nodes into the thoracic duct on the left or the right lymphatic duct. But

deviations from this basic arrangement frequently occur, consisting in short-cuts which may by pass one two or even three of the relay stations mentioned. Thus direct lymph drainage from the breast into the central apical or supraclavicular set may occur. In the latter case we have the clinical picture of enlarged supraclavicular nodes without involvement of the axilla a condition which in general is regarded as inoperable.

Radical surgery with removal of the two pectoralis muscles is predicated on the presence of a direct lymphatic channel from the superior portions of the breast to the apical nodes through the substance or along the deep surface of these muscles. Pressure on nerves in the axilla by enlarged nodes and interference with the lymph drainage of the arm resulting in edema are interesting by products of axillary metastasis which find their counterpart in nerve symptoms and edema in cancers of other regions.

Another clinically important point is illustrated in the opening up of atypical lymph channels after blockage of the usual lymphatic pathways. This is exemplified by occasional involvement of the inguinal lymph nodes in cancer of the breast. Of the greatest practical importance are pathways from the medial half of the breast to the other breast to the other axilla, and to the internal mammary nodes. Spread to these locations usually precludes surgical cure. The last named lymph nodes fortunately atrophy in older age thus eliminating this mode of cancer spread. The pleura and peritoneum are within reach of direct lymphatic involvement the pleura by communications with the lymphatics of the pectoral and intercostal muscles the peritoneum by way of lymphatics from the inferior and medial segment of the breast that anastomose through the linea alba with subperitoneal lymph plexuses.

PORTAL VEIN AND LYMPHATICS IN THE PROPAGATION OF TUMORS AND INFECTIONS OF THE GASTROINTESTINAL TRACT

So far we have presented avenues that illustrate the spread of infections in the venous system and of tumors through the lymphatic system. By contrast the portal circulation ex-

emplifies a pathway that is traveled by tumors and infections alike. It is one of the great natural highways along which infections and cancerous emboli may readily pass. Three unpaired arteries supply the gastrointestinal tract and its glands from the lower end of the esophagus to the upper portion of the rectum the celiac the superior and inferior mesenteric arteries. They ramify into smaller and smaller arteries and arterioles and finally break up into a capillary network in the wall of the intestines or within the glands. The blood then is collected by venules, which drain into larger and larger veins finally to form the splenic, the superior and inferior mesenteric veins. Their blood is poured into the portal vein which enters the liver and here forms another capillary system around the columns of liver cells. The portal vein thus drains an area in which infections as well as malignancies are very common. Among the infections appendicitis, ulcerations of the stomach duodenum and colon and diseases of the rectum such as proctitis and infected hemorrhoids deserve mention. It is particularly appendicitis which may lead to suppurative thrombophlebitis first of the tributaries of the portal vein and then of the portal vein itself. The incidence of portal thrombophlebitis in appendicitis varies according to Ochsner from 0.1 to 1 per cent of all cases. The pathway to the portal vein is by way of the appendiceal vein in the mesenteric fold of the appendix, the ileocecal vein and the superior mesenteric. Either by continuous growth of the septic thrombus along the venous channels into the liver or by detachment of a septic embolus from a thrombus in any of the veins mentioned single or multiple liver abscesses result. Septic embolism in the liver from a phlebitis in the appendiceal vein may occur without involvement of the intervening veins. Abscesses following appendicitis are usually multiple and are located in the right lobe of the liver. It has been pointed out, originally by French authors and later by others in this country that the portal vein contains two currents of venous blood, one coming from the superior mesenteric vein and going to the right lobe of the liver, the other from the splenic and inferior mesenteric veins passing into the left

may travel the same path. Peritonissillar infection may cause thrombophlebitis of the pharyngeal plexus and spread from there by way of emissary veins through foramina in the base of the skull likewise to the cavernous sinus. Erysipelas of the scalp may infect the superior longitudinal sinus through the parietal emissary vein. Most common is the involvement of the sigmoid sinus in mastoid infection which may spread to the sinus by way of a thrombophlebitis of the middle ear veins, by way of the lymphatics or by continuity directly from the infected mastoid bone (Braun). The emissary veins are also responsible for the fact that spread of infection from the dural sinuses into the general circulation cannot be prevented with certainty by ligation of the internal jugular vein since the infection may by pass the ligated vein by way of emissary veins in the region of the occiput which communicate with veins of the neck.

Attention has been called to an otitic hydrocephalus, complicating middle ear infection (Symonds, 1931). The condition characterized by bilateral papilledema and severe headaches, results from an increase in intra cranial pressure which is brought about by an infection of the sigmoid sinus and by spread of this infection to the superior longitudinal sinus. It is not so much the thrombosis of this sinus, but rather the thrombophlebitis, i.e. the infection of the sinus, which interferes with the absorption of the spinal fluid through the arachnoid villi and leads to rise in intra cranial pressure (Symonds, 1937). Symonds (1940) showed that infection in the neighborhood of the tonsils and in the nasopharynx may also lead to hydrocephalus by secondary involvement of the superior sagittal sinus. Thrombophlebitis of this sinus may then spread in retrograde direction into the superior cerebral veins which drain into this sinus and which supply the motor area of the brain. The results are cortical symptoms such as focal epilepsy and hemiplegia. Lately Martin has described a combination of increased intra cranial pressure and focal signs of cortical involvement such as convulsions and hemiplegia occurring in the first weeks of the puerperium. The disease may lead to recovery or death. The interesting point is that these so-called

thromboses of the venous sinuses and cerebral veins are actually emboli that by a devious pathway have been transported to the brain from pelvic veins, by passing lungs and other organs. This newly described avenue will be dealt with in later parts of this paper. Here it may suffice to point out that there is an important anastomosis between the veins of the vertebral canal and the dural sinuses through the great occipital foramen.

LYMPHATIC SPREAD OF CANCER OF THE BREAST

Having presented a location which exemplifies the venous spread of infection it may be appropriate to turn to another mode of propagation namely the lymphatic pathway and select a malignancy for illustration. An ideal representative is cancer of the breast, because it is so easily accessible to surgery and anatomical study. It was this location of cancer for which Sampson Handley developed his theory that cancer spreads centrifugally in all directions from its point of origin by permeation i.e. continuous invasion of lymphatic plexuses. While Handley's theory of continuous lymphatic spread to distant points in the organism is too dogmatic and narrow since it disregards lymphatic embolism and venous propagation of cancers, it nevertheless placed the operative treatment of cancer on a rational i.e. anatomical basis. It laid the scientific foundation for the radical surgical treatment of cancer of the breast which had been developed previously by Halsted on an empirical basis. Halsted's operation exemplified the fact that cancer can be cured even after it has spread from its primary focus to the regional lymph nodes, an experience which is borne out in other locations.

Since the pathways of metastatic spread of mammary cancer were discussed in detail in a previous paper (Lachman) only those facts shall be pointed out here that can be applied also to other areas where lymphatics are involved in the propagation of tumors. The principal lymphatic drainage of the breast passes from its subareolar plexus to the pectoral central and apical nodes of the axilla, and from there with or without interposition of supraclavicular nodes into the thoracic duct on the left or the right lymphatic duct. But

deviations from this basic arrangement frequently occur consisting in short-cuts which may by pass one two or even three of the relay stations mentioned. Thus direct lymph drainage from the breast into the central apical or supraclavicular set may occur. In the latter case we have the clinical picture of enlarged supraclavicular nodes without involvement of the axilla, a condition which in general is regarded as inoperable.

Radical surgery with removal of the two pectoralis muscles is predicated on the presence of a direct lymphatic channel from the superior portions of the breast to the apical nodes through the substance or along the deep surface of these muscles. Pressure on nerves in the axilla by enlarged nodes and interference with the lymph drainage of the arm resulting in edema are interesting by products of axillary metastasis which find their counterpart in nerve symptoms and edema in cancers of other regions.

Another clinically important point is illustrated in the opening up of atypical lymph channels after blockage of the usual lymphatic pathways. This is exemplified by occasional involvement of the inguinal lymph nodes in cancer of the breast. Of the greatest practical importance are pathways from the medial half of the breast to the other breast to the other axilla, and to the internal mammary nodes. Spread to these locations usually precludes surgical cure. The last named lymph nodes fortunately atrophy in older age thus eliminating this mode of cancer spread. The pleura and peritoneum are within reach of direct lymphatic involvement the pleura by communications with the lymphatics of the pectoral and intercostal muscles, the peritoneum by way of lymphatics from the inferior and medial segment of the breast that anastomose through the linea alba with subperitoneal lymph plexuses.

PORTAL VEIN AND LYMPHATICS IN THE PROPAGATION OF TUMORS AND INFECTIONS OF THE GASTROINTESTINAL TRACT

So far we have presented avenues that illustrate the spread of infections in the venous system and of tumors through the lymphatic system. By contrast the portal circulation ex-

emplifies a pathway that is traveled by tumors and infections alike. It is one of the great natural highways along which infections and cancerous emboli may readily pass. Three unpaired arteries supply the gastrointestinal tract and its glands from the lower end of the esophagus to the upper portion of the rectum the celiac, the superior and inferior mesenteric arteries. They ramify into smaller and smaller arteries and arterioles and finally break up into a capillary network in the wall of the intestines or within the glands. The blood then is collected by venules which drain into larger and larger veins finally to form the splenic, the superior and inferior mesenteric veins. Their blood is poured into the portal vein which enters the liver and here forms another capillary system around the columns of liver cells. The portal vein thus drains an area in which infections as well as malignancies are very common. Among the infections appendicitis ulcerations of the stomach duodenum and colon and diseases of the rectum such as proctitis and infected hemorrhoids deserve mention. It is particularly appendicitis which may lead to suppurative thrombophlebitis, first of the tributaries of the portal vein and then of the portal vein itself. The incidence of portal thrombophlebitis in appendicitis varies according to Ochsner from 0.1 to 1 per cent of all cases. The pathway to the portal vein is by way of the appendiceal vein in the mesenteric fold of the appendix, the ileocecal vein and the superior mesenteric. Either by continuous growth of the septic thrombus along the venous channels into the liver or by detachment of a septic embolus from a thrombus in any of the veins mentioned single or multiple liver abscesses result. Septic embolism in the liver from a phlebitis in the appendiceal vein may occur without involvement of the intervening veins. Abscesses following appendicitis are usually multiple and are located in the right lobe of the liver. It has been pointed out, originally by French authors and later by others in this country that the portal vein contains two currents of venous blood one coming from the superior mesenteric vein and going to the right lobe of the liver the other from the splenic and inferior mesenteric veins passing into the left

lobe so that abscesses and metastases of tumors would be located accordingly. In man there is definitely intermingling of blood so that too much reliance cannot be placed on this scheme.

Pyemic abscesses that are the result of appendiceal or intestinal infection may spread along intrahepatic vascular channels into the hepatic veins and from there by way of the inferior vena cava into the lungs and into the general circulation. In a recent clinical pathological conference reported in the *New England Journal of Medicine* a case was described in which following a postappendiceal abscess, pulmonary and hepatic abscesses occurred. The discussant postulated that the cecal abscess must have led to septic thrombosis of the iliac vein and embolism from there into the lung overlooking the fact that liver abscesses may readily spread into the lung following the natural venous drainage and that the introduction of an additional source of the septic pulmonary embolism was unnecessary. Surprisingly enough and anatomically without foundation, after the occurrence of the emboli in the lung and the diagnosis of the liver abscesses a ligation of the superficial femoral vein was done which of course was of no avail. Ligations of the tributaries of the portal vein particularly of the ileocolic vein in the presence of thrombosis, have been suggested in the literature but modern chemotherapy is the method of choice.

In passing the other modes of infection of the liver should be mentioned, since the liver is an ideal example for the multiplicity of sources of infectious spread. In addition to the transmission of septic emboli, the hepatic artery is frequently responsible for the settling of infections in the liver following infections of the general circulation such as osteomyelitis, endocarditis, carbuncles, respiratory infections, and pyemias from any source. A third source is direct ascending infection along the bile passages, also infections from the neighborhood such as paraneuritic and perinephritic abscesses. Occasionally lymphatics from the appendix and gall bladder may transmit infections and finally a retrograde spread from the head by way of the superior vena

cava, right heart, inferior vena cava, and hepatic veins has been reported.

Coming to the propagation of cancers to the liver we have the same organs of the gastrointestinal tract as sources of embolic spread and the same pathways, foremost among them the portal vein. Tumors concerned are, among others, cancers of the stomach, intestines including the rectum, and pancreas. There is an increasing tendency on the part of pathologists to regard cancerous spread by way of the blood stream as important as lymphatic propagation. Such an experienced observer as Miles who has pioneered the radical operation of rectal cancer has been proved wrong when he stated that for practical purposes we can disregard the occurrence of portal spread to the liver. We know now how common blood-borne metastasis is in cancer of the rectum. Often several generations of metastases may be found in the liver the first one being a localized metastasis brought to the liver by the portal vein which secondarily has led to showers of daughter metastases around it (Willis).

It has been said that intravascular invasion, i.e. invasion of the portal territory occurs in $\frac{1}{2}$ of all cancers of the lower colon and rectum. The higher the grade of malignancy the higher the incidence of venous involvement and the greater the chances of metastasis to the liver and from there to other organs. It seems that the vascular invasion is most apt to occur within the intestinal wall itself or within the perirectal tissue rather than at a distance. Thus early cancers may penetrate into the veins before they become locally inoperable (Glover and Waugh). The intravascular malignant thrombus encountered at necropsy or at operation is often found lying free within the lumen of the vessel and the ease with which it can become detached is very apparent (Dukes and Bussey). This represents a warning against rough handling of the tumor and rectum before vessels are ligated.

Evidence of tumorous growth within the hemorrhoidal veins is no absolute proof that the case is hopeless. But it is an indication that hematogenous spread is impending. Involvement of the veins with its danger of continuous or embolic spread of the malignant condition is an unpredictable event about

in the inguinopectineal region still prevails to a greater extent than we are prone to admit. Any doubt as to the validity of this statement can be resolved by interviewing our colleagues and junior surgeons. From Cooper's book it is not possible to obtain a clear understanding of this ligamentous structure. Seelig and Tuholake in their quest for more meticulous anatomical information on this ligament consulted, in addition to American and English texts many French and German anatomies. Surprisingly their investigation revealed that anatomists are not in complete agreement on what fascial structures conjoin to form Cooper's ligament. Moreover the anatomical drawings of this ligament are too frequently stereotyped and often devoid of structural correlation. Naturally with this paucity of knowledge and with scarcely any available references, there has been reluctance to adopt the use of Cooper's ligament especially when so much complacency exists as regards the results following repair with the inguinal ligament. Recently however Anson and McVay through anatomical research of the inguinal region, have contributed much toward clarifying our knowledge of Cooper's ligament. Their contributions have also enhanced our understanding of the relationship and continuity of the musculoaponeurotic strata of the inguinohypogastric region. Similarly they have traced the destiny of the enveloping fasciae of the parietal strata comprising the wall of the inguinal canal.

2 The multiplicity of names by which this ligament is identified—Cooper's, pectineal, iliopectineal pubic and superior pubic ligament—superimposes further confusion. In conformity to the early custom an anatomical structure was named after its discoverer. In this instance, Cooper not only was the discoverer of the ligament which bears his name, but he possessed the exceptional foresight of predicting its clinical application in the treatment of femoral hernia. While we do not wish to detract from Cooper's noteworthy achievements, in the interest of clarity it would be better that all proper names give way to anatomical nomenclature. The older literature leaned toward the terms 'pectineal' and 'iliopectineal', but the modern writers have developed a predilection for 'superior pubic' and 'pubic'. The latter tend to emphasize the entire underlying bone structure, the superior pubic ramus, while the former are more specific since they refer to an undisputed and universally recognized anatomical line of the ramus, the iliopectineal line or pecten. This line extends from the eminentia iliopectinea or iliopectineal junction to the pubic tubercle. Therefore, in a strictly anatomical sense

it would seem that iliopectineal is the preferable term for this ligament. It is realized that the Basle Nomina Anatomica has classified this ligament as the superior pubic.

3 The false complacency of surgeons concerning the results of the femoral, subinguinal, or inferior approach offered little incentive to developing other possible maneuvers in the hope of finding a better technique for the repair of femoral hernia. It was not realized that total extirpation of the peritoneal sac by this route is impossible. Actually only the excision of the subligamentous portion of the sac is possible and the surgeon is limited to a simple repair of the pectineal fascia. Both of these features are currently conceded as inadequate in our present concept of hernia repair. Furthermore in using the inferior approach the surgeon fails to take into consideration the genesis of femoral hernia, which is not infrequently a manifestation of a coexisting polylocular inguinal hernia. Consequently it is not possible to recognize, evaluate, or correct the composite saccular or coexisting mural deficiency of the inguinal region by the femoral route. In retrospect, the perpetuation of the latter technique has been based upon invalid premises and a misconception of its results. Incidentally this erroneous operative approach has retarded wider adoption of the superior or inguinal approach in the treatment of femoral hernia.

4 Possibly the most important deterrent to the acceptance of the Cooper's ligament technique has been the potential technical difficulties encountered because the ligament is deeply placed and the juxtaposition of the external iliac vessels creates the exaggerated fear of inadvertently puncturing them. The obturator vessels, if present, should be ligated for the occasional tearing of these vessels in the exposure of the pubic ramus will probably cause the surgeon more concern than the possibility of puncture of the iliofemoral vessels. By routine ligation of the inferior epigastric vessels, better exposure of Cooper's ligament is obtained, and in our experience we have encountered no complications attributable to this procedure. The placement of the most lateral sutures in Cooper's ligament may be slightly more hazardous than in the inguinal ligament for the surgeon who is undisciplined in hernial technique and not thoroughly familiar with the anatomy of this region. However these obstacles are mainly mental hazards which vanish with surgical experience and training.

5 The classification of inguinal hernia as given in most texts is misleading. For instance, the junior surgeon is taught that femoral hernia is a

which very little can be done except resort to surgery at the earliest possible moment. It is the spread to the regional lymphatics that determines the scope and technique of the operation. The anatomical investigations of Miles on the lymphatic propagation of rectal cancer have determined the radical surgical approach in the same way as the anatomical studies of Halsted and Handley have done for cancer of the breast. The principles of lymphatic spread are the same in the two conditions. Phenomena such as the by passing of lymph nodes by cancerous emboli or the reversal of the lymph stream in the presence of lymphatic obstruction with atypical involvement of nodes occur also in rectal cancer. The details of lymphatic drainage of the rectum and the mode of lymphatic spread of rectal cancer cannot be discussed here. But it is interesting to note that recently a reinvestigation of the lymph drainage of the highest portion of the rectum has been undertaken (Glover and Waugh). Based on the fact that the lymph stream from this part goes mainly upward along the superior hemorrhoidal vein the proposition has been put forth to restrict the extent of rectal resection in cancer of the upper portion and to preserve the sphincteric apparatus. Without wanting to enter into a discussion of the merits of the problem the anatomist is of course gratified to see that the pros and cons of the argument are offered on the basis of a study of the lymphatic anatomy of the region.

THE ANATOMICAL PRINCIPLES OF METASTATIC SPREAD

Having discussed some of the representative venous and lymphatic channels along which infections and tumors travel, it seems worthwhile to take up the subject of metastatic distribution from a more general angle and to dwell on the principles of tumor spread. Once a tumor has invaded the venous or lymphatic circulation, there exists the ever present danger of tumor particles becoming dislodged. After this has taken place the tumorous emboli are a cellular component of the blood or lymph stream and as such are transported wherever the current leads them. Their flow will be arrested at a site that depends on the

relative dimensions of vascular tube on the one hand and embolus on the other. Thus a metastatic embolus traveling in the general arterial stream reaches the smaller arterioles and is finally caught in the capillary network if the embolus is of sufficient size i.e. if it consists of more than a few cells. Somewhat more complex is the pathway through the liver. Two vascular channels the portal vein and the hepatic artery feed the capillary system of the liver and both are potential sources of metastatic emboli. Only one venous system the hepatic veins, drains this organ. Still more intricate is the arrangement in the lung. Here the pulmonary artery transmits venous blood which after oxygenation in the pulmonary capillaries is collected in the pulmonary veins and brought to the left heart and from there into the general arterial circulation. In addition the bronchial arteries and veins form their own capillary network in the wall of the bronchi. The two systems anastomose freely. Most metastatic emboli are transported to the lungs by way of the pulmonary artery and are arrested in the capillary system of the lung. Here they may or may not take root. If they do they may eventually break into the veins of the pulmonary or more rarely of the bronchial system. In the former case the emboli are transported into the general circulation in the latter they are returned to the lungs by way of the azygos or innominate veins superior vena cava, right heart, and pulmonary artery. Thus a new crop of pulmonary metastases may be set up as a result of this spread. Few emboli may also be brought to the lungs by way of the bronchial arteries from the general arterial circulation.

Figure 1 illustrates the capillary networks in a basic scheme of the circulation which has been developed by Walther. *a* is the capillary system of the lung the upper part of the ellipse represents the arterial side the lower part the venous side of the circulation. An embolus that enters the general circulation may be arrested in its capillary system (*c*) which is exemplified by the capillaries of the bone marrow the brain the skin the kidney or any organ that drains directly into the caval system. In the case of a lung tumor that has invaded the pulmonary veins, the sys-

Fig. Basic scheme of circulation. Heavy lines represent blood vessels containing arterial blood, double lines depict vessels containing venous blood, dotted lines lymphatics. *a*, Lung. *b* Liver. *c* Organs drained by vena cava. *d* Organs drained by portal vein. *e*, Regional lymph nodes. (Modified from Walther.)

temic capillary system is the first capillary filter which the embolus encounters. In contrast to this, an embolus that is dislodged from a cancerous thrombus in a peripheral vein is arrested in the capillary network of the lung (*a*). The systemic capillary network (*c*) then is the second filter for this tumor. *d* represents the capillary system of any organ that drains into the liver by way of the portal vein such as the stomach, intestines, pancreas, and spleen. *b* is the portal capillary system of the liver. A tumor of the gastrointestinal tract that breaks into a vein, spreads to the liver and from there to the lung. The lung is therefore the second filter for this tumor and the peripheral capillary network the third. We also see that tumor emboli traveling in the general circulation may be brought directly to the liver by way of the hepatic artery. This is demonstrated by the arc to the right of *d*. We further notice in this diagram the lymphatic drainage represented as coming from *b*, *c*, and *d* terminating in the venous circulation by way of the thoracic duct. *e* represents the system of interposed regional lymph nodes. Thus a tumor arising in the gastrointestinal tract may by pass the liver without metastasizing there and spread to the lungs via the lymphatics, the thoracic duct, superior vena cava, right heart, and pulmonary arteries.

According to this basic scheme there are then three or four types of metastatic spread (Walther) (1) The lung type whereby a tumor arising in the lung may break into the pulmonary vein and spread from there into the general arterial circulation (Fig. 2a). In this case the metastatic embolus could be arrested anywhere in the capillary bed of the periphery be it the skin, the bone marrow, the kidney, the liver or the brain. (2) The liver type (Fig. 2b). To this group belong the rare primary tumors of the liver for whom the first filter is the lung. (3) The vena cava type (the previous group is just a subheading of this group) (Fig. 3a) represented by all tumors that potentially break into and spread in the general venous circulation, i.e., most tumors, particularly those of the skin and its appendages—melanomas and breast cancers, tumors of the nervous system, nasopharynx, upper esophagus, lower rectum and anus, thyroid bones, and urogenital system. (4) The portal type (Fig. 3b) in which a tumor metastasizes to the liver by way of the portal vein then via hepatic veins, inferior vena cava, right heart, and pulmonary arteries to the lungs where a break through into the pulmonary veins leads to spread into the general circulation. The shunt around the liver directly to the lung via the lymphatics likewise occurs.

Fig. 2. Types of metastatic spread. a, left, Lung type. Tumor arising in the lung spreads after invasion of pulmonary vein, into general arterial circulation exemplified here by bone marrow, brain, and liver. b, Liver type. Primary tumor of liver spreads first to lung and from there as in a. (From Walther)

To see this scheme in its proper perspective one has to realize the importance and frequency of venous spread of cancer. According to Willis, it amounts to 50 per cent of all fatal cases. Once a metastasis has been set in any of the organs, it behaves like a primary tumor as far as the direction of its spread is concerned. It may easily break into a vein and set up a second generation of metastases. Thus different series of metastases may be superimposed and complicate the analysis (Willis).

An understanding of the pathways of lymphatic spread is somewhat complicated by the fact that once a lymph node is invaded it may be blocked and a collateral lymph flow may be opened up with reversal of the lymph current and involvement of atypical nodes (Taylor and Nathanson). Atypical nodes may also become cancerous by a rather devious route namely as a result of lymphatic spread from an organ that has become secondarily involved by way of the blood stream. Conversely metastatic cancer of the lymph nodes is apt to invade adjacent veins wherever these are in close proximity as e.g. in the neck, in the axilla, in the mediastinum, and in the pelvis.

Since we must assume from microscopic evidence at hand that many tumor emboli are considerably larger than the diameter of the

capillaries we can postulate that such emboli are arrested in the first capillary network they encounter. Consequently it is not surprising that the commonest sites of metastatic involvement are the liver and lungs since for most tumors these organs represent the first and second capillary filters encountered.

Taking into account all anatomical facts listed we generally have no difficulty to explain the pathway which a certain metastasis has taken. The difficulty usually arises in accounting for the noninvolvement of certain organs. Thus the lung occasionally escapes in cancer that has metastasized into the general circulation. Particularly in cancer of the breast and prostate do we sometimes find an isolated metastasis in the body far away from the primary focus yet without involvement of the lungs a fact which is not compatible with our scheme. Many theories have been offered to explain the abnormal location of metastases (Willis). Only a few shall be discussed here: (a) Paradoxical or crossed embolism. An open foramen ovale is supposed to explain the passage of tumor emboli from the systemic veins

Fig. 3. Types of metastatic spread, continued. a, left, Vena cava type, represented by all tumors that invade the general venous circulation and exemplified here by tumor of the uterus. directly into the arterial circulation by passing the lungs. This must be very rare since a functionally patent foramen ovale is a rather infrequent occurrence. (b) Retrograde venous embolism. Reversal of the blood flow in case of venous obstruction by a cancer may explain the presence of ovarian, vaginal, and epididymal metastases in case of renal tumor. (c) The noninvolvement of the lungs in case of systemic metastasis has been explained on the basis of the passage of individual tumor cells through the pulmonary capillaries without arrest. While this may occur probably the breaking off of clusters of tumor cells larger in diameter than the cross section of the pulmonary capillaries is more common. But it has to be realized that gross anatomical evidence of the absence of tumor tissue in the lungs does not prove noninvolvement of the lungs. In many cases careful microscopic search will reveal the presence of small emboli in the pulmonary arterioles.

THE VERTEBRAL VENOUS PLEXUS AND ITS SHARE IN THE SPREAD OF TUMORS AND IN INFECTIONS

In recent years experimental and clinical proof has been offered for a pathway we were hardly aware of but which removes many of the difficulties that are encountered in explaining the spread of metastasis and infection (Batson). As stated before, it is particularly the isolated involvement of the skeleton in metastatic spread of cancer of the breast and prostate which has baffled observers. How can metastatic emboli from the prostate reach the spinal column without being arrested in the lungs? In answer to this question Batson called attention to a large venous system within and outside the spinal canal extending from the head to the sacrum which had been described a century ago by the Frenchman, Breschet, and by German authors, but had since been forgotten (quoted from Harris). As these authors showed there is a rich plexus of segmental veins on the outside of the spinal column anteriorly and posteriorly as well as inside the spinal canal. These veins also surround the spinal nerves within the intervertebral foramina and thus act as a cushion for the spinal nerves and the spinal cord. Another

characteristic feature is the rich anastomoses of these veins, particularly in a longitudinal direction but also the cross communications between right and left and from the inside of the canal to the outside. These veins are valveless and anastomose above with the cranial venous sinuses and below with the hypogastric veins.

In his experiments on human cadavers and later on live rhesus monkeys, Batson injected the dorsal vein of the penis with dyes and opaque media and found that the dye in addition to going to the inferior vena cava also entered the spinal veins and the vertebral plexus depending on the position of the body and on the viscosity and amount of material injected. After injection of 200 cubic centimeters of a thin mass the contrast medium did not fill the vena cava but went along the vertebral veins to the skull. Repeated injections confirmed this and demonstrated filling of the venous sinuses of the cranial cavity. In the live monkey after injection of thorotrast into the dorsal vein of the penis, filling of the caval system by way of the hypogastric and common iliac veins was noticed. Imitating the changed pressure conditions that take place in straining coughing sneezing a towel was tied around the abdomen of the animal with the result that the contrast medium entered the vertebral veins. Injection into a venule of the breast of female cadavers led to extensive filling of vertebral veins and sinuses of the skull by way of the intercostal veins. The veins of the shoulder girdle and the vasa vasorum down to the elbow were likewise demonstrated.

Thus we have to regard the vertebral venous system as a plexus which contains a considerable amount of blood, more than is necessary for drainage of the organs it surrounds. It acts as a reservoir a function which is facilitated by the absence of valves, by the rich anastomoses with other body veins and by its plexiform arrangement. We have to assume that the blood flow in this system is easily reversed following changing pressure conditions such as take place in straining. Batson's experiments demonstrate how freely the blood of the prostatic plexus and of the veins of the breast enters the vertebral plexus by-passing the systemic, pulmonary and

portal circulation. This then is undoubtedly the pathway that is taken by cancerous emboli from the prostate to the pelvis and spinal column. It is in all probability also the channel used in the spread of carcinoma of the breast to the skeleton. Work by other investigators (Collis) has confirmed a path from the lung and pleura by way of the bronchial and intercostal veins and vertebral veins to the brain thus explaining the frequent occurrence of brain abscess in pulmonary infections and empyema, and metastasis to the skull and brain in pulmonary cancer. We now also understand the involvement of the cranial venous sinuses in puerperal fever which was mentioned in the beginning (Martin).

The recent investigations on the vertebral venous system have cleared up many of the difficulties in understanding the distribution pattern of cancerous and infectious emboli.

Having discussed the highways and byways along which metastatic spread takes place one basic fact still needs to be pointed out: mechanical arrest of a tumor embolus is not identical with transformation of this embolus into a florid metastasis. Many emboli apparently never take. We have to assume that tumor particles of sufficient size, once they have reached the general circulation are deposited indiscriminately anywhere where the blood stream leads them and that their arrest is determined only by the relative size of the embolus and the capillaries it traverses. Why then we must ask ourselves are metastases so rare in certain locations such as skeletal muscles, the heart, spleen, the wall of the intestine all of which have such a rich blood supply? And why is metastasis so common in other locations? Mechanical factors and reasons of vascular anatomy are insufficient to

furnish an explanation although it has been attempted on this basis. Tissue susceptibility on one hand and general and local resistance on the other must be instrumental in determining the selection of metastatic sites. Experimental evidence on tissue cultures point to chemical factors such as oxygen tension, hydrogen ion concentration, and the accessibility of growth promoting hormones in the tissues as being responsible for the distribution of metastases (Willis). Recognizing that he has done his share once the roads of metastatic spread have been clarified, the anatomist leaves these problems to the biochemist and the cancer pathologist.

(52.5 per cent) of the 200 jaundiced cases, common duct stones were not found at operation. One hundred eighty six cases had proved common duct stones but almost one half (89 or 47.8 per cent) of these patients with common duct stones did not have jaundice. Painless jaundice occurred in 2 patients with common duct stones.

From these figures it appears that jaundice indicates common duct stones in only 50 per cent of the cases. In the other 50 per cent, the jaundice was the result of an associated hepatitis or cholangitis. The presence or absence of jaundice is an important but a treacherous sign. Fifty per cent of patients who have common duct stones do not have jaundice and in only 50 per cent of patients with jaundice have common duct stones been discovered.

The physical findings depended usually on the extent of the pathologic process. There was considerable spasm and rigidity over the right upper part of the abdomen in acute disease of the gall bladder. In a few instances a diagnosis of acute cholecystitis was made on the basis of physical findings and chronic gall bladder disease was found at operation and vice versa. Empyema of the gall bladder has been found when chronic cholelithiasis was expected.

ROENTGENOLOGIC EXAMINATION

Either oral or intravenous cholecystographic examination of the gall bladder was made in 910 of the 1104 cases (82.4 per cent). One hundred ninety four patients had no roentgenologic examination. The cases not examined included those in which gallstones were an incidental finding, many who had secondary biliary tract operations and some with jaundice in which it was not thought of value to give the dye.

A correct diagnosis was made in 888 of the 910 patients (97.6 per cent) examined roentgenologically. In 559 cases (61.4 per cent) the gall bladder dye. In 197 cases (21.6 per cent) a diagnosis of nonfunctioning gall bladder was made and in all of these cases stones were found at operation. In 25 cases (2.7 per cent) a diagnosis of nonfunctioning gall bladder was made and no stones were found at

laparotomy, but 19 of these cases had microscopically proved chronic cholecystitis. Many of these were of the cholesterosis or strawberry group. The roentgenologic diagnosis of common duct stone was made and proved at operation in only 2 cases.

Right-sided renal calculi plus gallstones occurred in 2 patients and the renal stones were later proved to be present by retrograde pyelograms. A diagnosis of situs transversus was made in 2 cases and cholecystectomy was done through a left upper rectus incision. Pancreatic lithiasis was suspected once and proved by subsequent operation.

A diagnosis of irritable bowel or functional indigestion associated with gall bladder disease was made in 132 patients (12 per cent) of the total number of the 1104 patients. These patients were all treated before and after the gall bladder operation for this condition.

Roentgenologic studies were misleading or erroneous in 22 (2.4 per cent) of the 910 patients examined. Twelve patients had normal cholecystograms, 5 of these had stones at operation and the remaining 7 had chronic cholecystitis. In 8 cases the cholecystogram was interpreted as showing cholelithiasis but no stones were found at operation. A diagnosis of nonfunctioning gall bladder was made in 1 case in which a normal gall bladder was found at laparotomy. An x ray diagnosis of papilloma of the gall bladder was made in 1 case but not found at operation.

Because of the generally poor results from cholecystectomy for noncalculous cholecystitis before a surgical procedure is proposed in cases of faulty visualization of the gall bladder without demonstrable stones, certain criteria must be met (34-49): (1) all other likely causes for the symptoms have been eliminated; (2) there is sufficient pain to warrant an attempt at relief by cholecystectomy; (3) a cholecystogram is abnormal on at least two tests.

Medical treatment of suspected or confirmed coexisting digestive disturbances has failed to relieve the symptoms.

PREVIOUS SURGERY

One hundred fourteen patients (10.3 per cent) had had previous biliary tract surgery.

distinct entity apart from inguinal hernia. In reality a femoral hernia is simply a variant of the peritoneal sac in which a locule makes its exit through a patent femoral ring. There is no embryonal basis for assuming that the femoral locule arises from a preformed peritoneal vestige as obtains in indirect hernia. McClure and Falls found in a series of 90 femoral hernias that 22.3 per cent of the patients had undergone repair of inguinal hernia previously. Such a high incidence of femoral locules in recurrent inguinal hernias points convincingly to the probability that femoral locules are frequently not diligently searched for and consequently overlooked at the time of the initial repair. Similarly Burton and Ramos in an analysis of 131 recurrent hernias found a much higher incidence of coexisting locules than were encountered in primary hernias. In this series there was an incidence of 13.8 per cent of diverticular locules as compared to 2.6 per cent in 2,303 primary hernias. Such a wide discrepancy of hernias strikingly illustrates the necessity of thorough digital exploration of the peritoneal sac for coexisting variants. These statistical data should be convincing evidence of the rationale of the inguinal route in the treatment of all inguinofemoral hernias. The contention that the femoral variant cannot be delivered from the superior approach is not valid. In our series of 100 repairs with Cooper's ligament no modification of the usual oblique skin incision of the inguinal region was necessary. In those femoral hernias which are incarcerated or strangulated the imprisoned bowel can be examined before it disappears into the abdomen. This is another advantage of the inguinal over the femoral route. In rare instances the lateral margin of the lacunar ligament may require sectioning to facilitate reduction.

6. Another important contributing factor which is retarding the acceptance of repair with Cooper's ligament is the failure to establish definite criteria for its employment. Most articles on the radical treatment of hernia have dealt almost exclusively with the technical phase of the operation and have omitted any discussion of the indications for the particular technical procedure. With emphasis on the criteria for the respective operative techniques, there is greater likelihood that the selected repair will be more physiological, more rational, and ultimately more successful.

CRITERIA FOR THE EMPLOYMENT OF COOPER'S LIGAMENT

1. Femoral loculation of the sac.
2. Insufficiency of the inguinal ligament.

3. Marked laxy of the parietal strata.
4. Arborization of the sac.
5. Multiple interfascicular defects with fascial incompetency.

For an operation to be successful recognition of its indications is just as essential as correct execution of the various maneuvers of its technique. Progress in surgery depends not only on the increasingly efficient application of advanced knowledge and techniques but also on the constant acquisition of new information. The failure to establish and to define clearly the criteria for the major phases of hernial operations, namely herniotomy, herniorrhaphy and hernioplasty is perhaps the most important factor contributing to existing confusion regarding the practical application of the fundamental principles underlying the numerous hernial operations. A common denominator embodying certain limitations in which the less experienced can safely follow should be available. The general acceptance of such a concept would promote standardization of a retinue of techniques and aid in comparative statistical studies. Therefore the criteria as proposed for the employment of Cooper's ligament are only intended to serve as a guide, allowing, of course, the judgment and experience of the surgeon.

1. *Femoral loculation of the sac.* All inguinal hernias have a peritoneal sac. The sac may have one or more outpouchings or locules. It is the anatomical location of the initial exit of the locule and/or locules that determines the type of hernia. For instance, if a locule of the sac protrudes through the femoral ring into the canal it is known as a femoral hernia. Actually it is simply one variant of the sac. There may be other coexisting locules. Unfortunately most textbooks of surgery and many articles in the current surgical journals classify femoral hernia as a separate entity distinct from inguinal hernia. The responsibility for this erroneous conception and in a large measure for its irrational treatment is traceable to the

The total excision of the sac inclusive of its locules is the first prerequisite to the cure of any hernia. This dictum of Bassini and Halsted (16) is equally true today. In small indirect hernias with no coexisting mural weakness, this maneuver will suffice. However in the presence of other variants of the sac or concomitant parietal defects, additive reinforcement of the wall is imperative. Therefore, with our present knowledge of the mural and saccular embryogeneses of hernia, it logically follows that any technique which does not completely expose the structures of the inguinal canal and

tomy was done and in only 2 of the cases was it found necessary to repair the hernia.

Cholelithiasis was also found in conjunction with ulcerative colitis, regional ileitis, sigmoid diverticulitis and rheumatoid arthritis. A cholecystectomy was done in an attempt to relieve the symptoms in these conditions.

No attempt was made in this series to tabulate the correlation between heart disease and cholelithiasis. Hurxthal and Dolgin have recently reviewed 559 cases of proved cholecystitis and cholelithiasis and found that 53 patients (9.5 per cent) had associated heart disease. Their impression is that the incidence of heart disease is not any higher in patients with gall bladder disease than it is in any other group of patients of the same age or sex distribution. They state that cholelithiasis may be responsible for varied electrocardiographic changes, but they do not believe that cholecystectomy will have any effect on the heart disease itself other than to eliminate the electrocardiographic findings caused by the cholelithiasis. Distinction between acute gall bladder disease and heart disease is at times difficult but usually by careful study the differential diagnosis can be made.

TUMORS OF THE GALL BLADDER

Tumors of the gall bladder are not common. Only 4 tumors were found in 1,036 cholecystectomies as follows: 1 benign papilloma, 1 malignant adenoma, and 2 adenocarcinomas. The incidence of carcinoma in this series is only 0.3 per cent. This is much lower than in a previously reported series (41) and a series by Vadheim Gray and Dockerty. In 3 of the 4 cases a diagnosis of cholelithiasis was made from the roentgenogram and the fourth patient who had a benign papilloma was operated on for acute cholecystitis. All 4 of these patients were operated on and all had gall stones. The incidence of gallstones with carcinoma in this series was 100 per cent while others (5, 22, 29, 36, 37, 42) report an incidence of 76 to 87 per cent. When the diagnosis is made preoperatively the lesion is usually too extensive for any chance of cure. Cases correctly diagnosed preoperatively as carcinoma of the gall bladder are not included in this report.

COMMON AND HEPATIC DUCT STONES

The philosophy of our surgical staff in regard to exploration of the common bile duct has been stated and restated (8, 9, 12, 30, 35). The present study corroborates our previous experiences (9) that there is no certain way to tell whether or not common duct stones are present. Suggestive points are often found in the history, physical examination, and at operation which lead one to believe that common duct stones are present or absent. Neither the mortality nor the morbidity is appreciably increased with common duct exploration, especially with the anesthesia (43) and preoperative preparation (1) employed at the present time. We believe therefore, that the common duct should be explored for any of the following indications: (1) frequent acute attacks of biliary colic, chills or fever; (2) past or present history of obstructive jaundice or laboratory signs thereof; (3) dilated or thickened common duct; (4) multiple small stones in the gall bladder; (5) unsatisfactory or suspicious findings on palpation; (6) sediment in aspirated bile from the common duct; (7) non-calculous gall bladder with biliary tract symptoms; (8) small contracted gall bladder; (9) acute or subacute pancreatitis or hepatitis.

The common duct was explored in 504 cases (45.7 per cent) and stones were found in 186 cases (16.8 per cent), 36.9 per cent of the ducts explored contained stones. There were 161 cases of cholelithiasis and common duct stones, 17 cases of common duct stones after previous cholecystectomy (done elsewhere) and 4 each of common duct stones with cystic duct remnant and with fibrosis of the sphincter of Oddi.

Occasionally one will find a dilated common duct and ampulla associated with cholelithiasis but no common duct stones. In these cases there usually are other indications for cholecystectomy besides dilatation of the duct. We believe the recent passage of a common duct stone is frequently the explanation of such a finding. Also patients may give a typical history of recurrent common duct stones and exploration will yield negative results. This occurred 6 times in this series.

Foreign bodies in addition to stones in the common duct are rare. Manson, Bahr and

SURGERY GYNECOLOGY AND OBSTETRICS

Walton reported the removal of a liver fluke from the common duct and Crawford reported an autopsy in which the blade of a hemostat was found in the common duct 7 years after a cholecystectomy. Removal of a broken T tube relieved recurrent obstruction of the common duct in 1 case in this series.

PANCREATITIS AND BILIARY TRACT DISEASE

Pancreatitis was found to be associated with biliary tract disease in 26 cases (2.35 per cent). The etiology of pancreatitis is quite generally considered to be the reflux of bile or pancreatic juice into the pancreatic duct caused either by a stone impacted in the ampulla of Vater or by anatomical variations in which both the duct of Wirsung and common bile duct open into the ampulla (47). In this type of relationship any spasm of the sphincter of Oddi may cause a diversion of the biliary flow. Also in certain instances there may be a hyperplasia of the epithelium of the pancreatic duct with an obstruction to the flow of pancreatic fluid resulting in varying degrees of pancreatitis (47).

It has been our experience in the past (8, 22, 31) that direct surgery on the pancreas itself is rarely indicated. We do not believe that it is wise to incise or drain the pancreas. We consider pancreatitis to be a complication of disease of the biliary tract and therefore we usually drain the common bile duct and remove the gall bladder if indicated (33).

A diagnosis of interstitial pancreatitis or chronic pancreatitis is rarely made preoperatively and when found is merely more evidence for cholecystectomy. Patients with acute hemorrhagic pancreatitis are rarely operated upon in the acute stage as early surgery in these cases carries a very high mortality risk. When acute cholecystitis occurs in conjunction with acute interstitial pancreatitis, the diagnosis may be difficult and delay in surgery may be fatal.

In this series pancreatitis was found with cholelithiasis and a normal common duct in 8 cases and with chronic cholecystitis and a normal common duct in 5 cases. Chronic pancreatitis was found together with stricture of the common duct in 1 case similar to those cases reported by Peterson and Cole.

INTERNAL BILIARY FISTULA

An internal biliary fistula occurs more commonly than is generally thought. There were 16 cases in this series. They may be classified into two groups as spontaneous, and as those caused by a previous surgical procedure.

Spontaneous biliary fistula has been adequately reported by others (17, 50). This condition is rarely considered as a preoperative diagnosis unless there has been a history of passage of gallstones by rectum, or an intestinal obstruction caused by an impacted gallstone (40). Also a severe attack of biliary colic is sometimes followed by a period during which the patient is free of symptoms. This sequence is suggestive of a spontaneous fistula, especially if the patient has a long preceding history of disease of the biliary tract. If there is air in the biliary tree or if barium is seen in the biliary system during gastrointestinal examination this is presumptive evidence of an internal fistula.

A previous surgical procedure was the cause of a biliary fistula in 4 of our cases. Two patients had had a cholecystectomy and two others a choledochoduodenostomy.

Ten of the patients with a spontaneous fistula had connections between the gall bladder and duodenum, 1 between the gall bladder and colon and 1 between the gall bladder and common duct.

It is advisable to close the fistula at the time of cholecystectomy, otherwise complications may arise such as ascending cholangitis, which occurred in 2 cases in this series.

BENIGN STRUCTURES OF THE BILE DUCT

Benign strictures of the bile duct comprise but a small group (23 cases) in this series and are mentioned only because a diagnosis was made of associated biliary calculi. In many of these cases a diagnosis was made of recurrent or residual stones of the common duct. This number is but a small percentage of the strictures that have been seen at the Lahey Clinic during the past few years. As of December 31, 1945, 176 patients had been referred here and operated upon for stricture of the common bile duct (6).

The causes and methods of repair used have been presented by Cattell (10) however it

might be well to review them briefly at this time. The causes are (1) ulceration from gallstones (2) inflammation of common bile duct (3) operative injuries (a) excision of portion of duct (b) clamping during operative hemorrhage (4) following subtotal gastrectomy (5) chronic sclerosing pancreatitis

By far the most common cause of stricture is operative injury which comprises over 80 per cent of the cases.

The prevention of benign strictures as far as operative injury is concerned is based mainly on adequate exposure (32) so that a careful anatomical dissection can be carried out. Lahey has mentioned this fact many times (30-33 35)

The diagnosis of stricture is often difficult to make it is frequently confused with common duct stones or carcinoma of the bile duct or pancreas. If after a cholecystectomy jaundice develops immediately (in 1 to 3 weeks) or if the fistula at the site of the T tube drains over a long period of time and if in addition there is a history of operative injury or hemorrhage a stricture probably is present. Patients with stricture gradually become jaundiced following the closure of the external biliary fistula and usually remain so until another operation is done or an internal fistula develops in the interim

Twenty three strictures of the bile duct were encountered in this series 4 had been caused by operative injury 1 by cholangitis, 17 by fibrosis of the sphincter of Oddi and 1 by fibrosis of the cystic duct and chronic cholecystitis.

Fibrosis of the sphincter of Oddi is not an uncommon condition it was found in 17 cases in this small series. It occurs usually following previous bile duct surgery in which the sphincter may have been dilated too vigorously. As proof that this is not always the cause however it was present in 2 cases in which the patients had not had previous surgery and only 1 of these patients had common duct stones.

POSTCHOLECYSTECTOMY SYNDROME

The causes of symptoms following cholecystectomy with or without choledochostomy are many. Various aspects of this subject

have been discussed by numerous authors (7, 11 13 14, 16 21 24, 25 28, 44 53, 54). The different causes as they were found in this series are briefly outlined (1) benign stricture of common duct (2) residual pancreatitis or hepatic disease (3) common duct stones (4) irritable bowel or functional indigestion (132 cases), (5) gall bladder or cystic duct remnant (12 cases) (6) biliary dyskinesia and spastic sphincter of Oddi (7 cases) (7) adhesions of duodenum to gall bladder fossa (8 cases), (8) duodenal diverticulum simulating gall bladder colic

The first three causes have been discussed elsewhere in this paper

Irritable colon or functional indigestion was present in 12 per cent of the cases. A diagnosis of this condition was usually made preoperatively and medical therapy instituted. According to Ivy and Goldman constipation may cause stimulation of various splanchnic nerves and predispose to stasis of the biliary tract by decreasing bile formation and by increasing the resistance to the flow of bile through the sphincter of Oddi into the duodenum. Wilkinson stated that symptoms of irritable colon are just as varied as those of cholecystitis. There may be epigastric distress, belching distention, shifting abdominal pain and nausea and vomiting. Recognition and treatment of this condition will decrease the incidence of poor results after cholecystectomy particularly in that group of patients who complain of dyspepsia alone.

A remnant of the gall bladder or cystic duct has been recognized for several years (12 21) as a possible cause of distress after cholecystectomy. We believe that, with adequate exposure and anatomical dissection, such a surgical error can always be avoided. In this series there were 12 cases 7 with stone in the remnant and no common duct stones, 4 cases with a remnant without stone and choledocholithiasis and 1 case in which stones were found in the remnant and the common duct was not explored. One should be able to achieve a good result by removing the cystic duct remnant if the first operation were clearly indicated (21)

We consider biliary dyskinesia and spastic sphincter of Oddi in the same category. The

SURGERY GYNECOLOGY AND OBSTETRICS

cause of this condition is not definitely known. Mild symptoms of dyskinesia are undoubtedly more frequent than our few cases would indicate. The only patients who were operated on in this group were those who did not respond to strict medical management. There were 7 patients, 2 with jaundice without common duct stones and 5 with no jaundice and no common duct stones.

Adhesions of the duodenum to the gall bladder fossa following cholecystectomy constitute a condition about which very little is written. This condition is very common, but rarely causes severe symptoms. It is usually recognized only at operation the symptoms having been thought to be caused by common duct stone or stricture. The duodenum is firmly adherent and usually rotated so it may partially obstruct both the duodenum and the common duct. There were 8 cases in this series in which symptoms occurred. All 8 patients had pain in the right upper quadrant either intermittently or constantly all had occasional nausea and vomiting and there was a history of jaundice in 2 of the cases. All were relieved by release of the adherent duodenum and by placing the omentum in the fossa so that the adhesions would not recur.

In order to prevent this complication one should carefully repentonealize the gall bladder fossa and common duct and then place a small portion of the omentum in this region between the liver and duodenum.

Duodenal diverticula are usually symptomless. They were found to be associated with biliary tract disease in 9 cases. It is not believed necessary to resect them unless they have a very narrow neck. Resection was done only once (together with cholecystectomy) in this series. In 1 case which has already been reported (24) the diverticulum was not found until the fourth abdominal operation. This diverticulum contained gallstones and had a narrow neck. Resection of the diverticulum gave complete relief.

SURGICAL PROCEDURES

Cholecystostomy was done in only very ill patients who had some other complicating disease. Drainage of the gall bladder was done in 6 cases (0.54 per cent) and all were for

acute cholecystitis. This incidence is much lower than any other reported series of cases known to us. Cholecystectomy alone was done in 583 cases. Cholecystectomy with choledochotomy was done in 454 cases.

There were 114 patients who had secondary surgery of the biliary tract. Three patients had operation directed toward the treatment of peptic ulcer along with cholecystectomy; 2 a gastric resection, and 2 had gastroenterotomy.

In 9 cases cholecystectomy was performed for acute cholecystitis occurring during the immediate postoperative course of some other condition 3 after abdominoperineal resection, 2 after thyroidectomy, 2 after transthoracic resection of the esophagus, 1 each after a peptic laparotomy and a transurethral resection. Appendectomy was performed in conjunction with the biliary tract surgery in 400 cases. We do not believe that appendectomy increases the mortality or morbidity. During the pathologic examination in one of the appendectomy cases, a carcinoid of the appendix was discovered.

POSTOPERATIVE COMPLICATIONS

Seventy two of the 1104 patients (6.5 per cent) had postoperative complications.

Stricture of the bile duct thought to have been caused by operative injury occurred in 1 case. Inflammatory stricture occurred in 1 case. This patient had a small but grossly thickened and acutely inflamed common duct at the time of initial operation when stones were removed from the duct and a contracted gangrenous gall bladder was removed. A T tube was inserted, but this became plugged and had to be withdrawn. In the course of the next 3 months fibrous stenosis of the middle third of the common duct developed through which a 1 millimeter lumen persisted. At a second operation the stenotic portion was resected and the ends anastomosed over a viatum tube.

Atelectasis or pneumonia or both was a complication in 10 patients (0.9 per cent). Phlebitis or phlebotrombosis developed during the immediate postoperative period in 16 patients (1.45 per cent). Eight patients

had pulmonary emboli 2 fatal and 6 nonfatal. One pulmonary embolus occurred shortly after a varicose vein ligation and retrograde injection 13 days after the cholecystectomy. None of the patients with pulmonary emboli had clinically detected evidence of phlebitis.

Major wound infection occurred in 7 patients 3 of these had cholecystectomy and appendectomy 1 had appendectomy and choledochostomy and 3 had simple cholecystectomy. The abdominal drains emerged through the primary incision in all of these cases.

Right subdiaphragmatic abscess occurred in 1 case and there was 1 left subdiaphragmatic abscess in a case of situs transversus in which a pseudodiverticulum of the transverse colon was excised in addition to cholecystectomy. There was 1 patient who had a right subhepatic and right subdiaphragmatic abscess appendectomy and cholecystectomy were done in this case.

Two patients had wound dehiscence 1 of these had cholecystectomy appendectomy and choledochostomy with choledocholithiasis.

Hernia in the scar occurred in 16 cases (1.45 per cent). One patient had associated wound infection, 5 had cholecystectomy and appendectomy 1 had cholecystectomy and choledochostomy without common duct stones and 1 had secondary biliary tract surgery.

Bacillus welchii peritonitis occurred in 1 patient and was fatal. This rare complication has been reported before (2). There have been only 3 cases in 5 000 operations on the biliary tract. It is thought to be caused by reflux of infected duodenal contents into the common duct after dilatation and irrigation of the common duct with isotonic solution of sodium chloride. We now advise that the catheter used be kept in the common duct and not be passed through to the duodenum and only moderate dilatation of the sphincter be done.

There were 2 patients who had an exacerbation of gout during their postoperative convalescence. Two had parotitis.

One patient had a massive gastric hemorrhage on his fourteenth postoperative day and a posterior gastroenterostomy was done. He now has symptoms of a jejunal ulcer.

MORTALITY RATE AND ANALYSIS OF DEATHS

There were 1104 operations, 10 deaths making a mortality rate of 0.9 per cent.

Analysis of deaths. One death occurred in a woman 62 years old who had cholelithiasis choledocholithiasis, and a diaphragmatic hernia which was repaired at the time of the cholecystectomy and choledochostomy. She died on the twelfth postoperative day. Autopsy showed *Bacillus welchii* peritonitis pancreatitis and cerebral thrombosis.

Death occurred in a 28 year old man with cholelithiasis in whom cardiac arrest took place after a spinal anesthesia. He died on the fifteenth postoperative day of pneumonia and lung abscess.

A third death was in a 65 year old woman who had cholelithiasis, choledocholithiasis, and duodenal ulcer. She had a cholecystectomy choledochostomy and subtotal gastric resection. Death occurred on the fourth postoperative day of bronchopneumonia.

A fourth death was in a 63 year old man who had acute cholecystitis with common duct stone. While getting out of bed 12 days after cholecystectomy and choledochostomy he had a massive pulmonary embolus.

The fifth death was in a 55 year old man with interstitial pancreatitis and cholelithiasis. He died on the eleventh postoperative day after cholecystectomy and choledochostomy of massive pulmonary embolus confirmed by autopsy.

The sixth death occurred in a 50 year old man with cholelithiasis he had a hemoptysis 36 hours postoperatively which was thought to be caused by a pulmonary embolus. He died shortly thereafter and autopsy showed massive lobar atelectasis secondary to a large mucous plug in a primary bronchus.

A 65 year old woman with cholelithiasis had a cholecystectomy and died on the seventh postoperative day of coronary occlusion the diagnosis being corroborated by an electrocardiogram.

A 74 year old man with acute cholecystitis died 24 hours after cholecystectomy. Autopsy was not performed death was thought to be caused by liver failure.

A 50 year old woman with a cystic duct remnant, chronic pancreatitis and hepatitis

died 24 hours after excision of the cystic duct remnant and a choledochostomy. No autopsy was obtained. Death was thought to be caused by "liver failure."

A 57 year old man had had 3 previous operations and was in very poor condition from a gastropancreaticoduodenal cutaneous fistula. He died on the thirteenth postoperative day after cholecystectomy, choledochostomy, closure of a gastric fistula, and drainage of a pancreatic fistula and cyst. There was a large mass in the head of the pancreas. Curettage of the base of the pancreatic tumor showed mucinous carcinomas of pancreas. No autopsy was obtained.

A STANDARDIZED METHOD FOR ASSESSING THE STRENGTH OF HAND AND FOOT MUSCLES

F H. LEWEY M.D., W G KUHN Jr., M.D., and J T JUDITSKI

SATISFACTORY examination and periodic re-examination of large groups of patients with injuries to the peripheral nerves calls for a standardized method of measuring muscle strength. The method should be simple and rapid. The results should be reproducible and permit, in the hands of different examiners, the accurate evaluation of change in function. This is clearly a practical problem in contrast to the physiologic attempts to determine in the strict sense, the power of a single muscle in foot pounds or kilogram meters. Hence no reference will be made to this literature.

Our interest was concentrated on the muscles of hand, fingers, foot and toes. It was our desire to measure instead of estimate the resistance a patient could muster by contracting a group of muscles supplied by one nerve trunk. We decided to explore the reliability and the reproducible character of measurements obtained with the common spring scale, a device readily adapted to the movements of the extremities.

From the Neurologic Neurosurgical Sections, Cushing General Hospital, Framingham, Mass. and the Department of Neurosurgery, Graduate School of Medicine, University of Pennsylvania.

Lovett, studying patients with infantile paralysis seems to have been the first to make systematic use of the spring scale for measuring muscle function. Martin on Lovett's suggestion developed the method in the Physiological Institute of Harvard. Tables of standard muscle strength were established for all groups of muscles of normal children for ages from 4 to 16 years. Successive tests at short intervals showed the readings as to individual muscle groups to be in a large percentage of cases remarkably constant. Pollock used this method in nerve injuries during the first world war. Unfortunately no one seems to have followed his good example.

The figures gained in our examinations would be of limited practical value unless expressed in percentage of a certain norm. This brought up the old question of the yard stick of normalcy. At first we took for comparison, the corresponding muscle group of the patient's normal side. This doubled the time of examination and gave altogether unsatisfactory results since some patients had developed unusual muscle strength on the normal side as a compensatory factor.

Fig. 1. Spring scales and appliances for measuring muscle strength. For their application see Figures 2 to 5.

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE L—AVERAGE STRENGTH OF MOTIONS OF A HOSPITAL POPULATION
EXPRESSED IN POUNDS (450 GRAMS)

		Upper Extremity			
		Mean M	Standard deviation of Mean SD	Standard error of mean SE _M	Range for normal M ₄₅₀ SD
Median nerve	Index			.5	10—14½
	Flexion, and phalanx (flexor digiti profundus)	4	1.0	5	10½—14½
	Flexion, and phalanx (flexor pollicis longus)	3	5	5	10½—14½
Thumb	Flexion, and phalanx (flexor pollicis brevis)	9		5	10½—14½
	Flexion prox phalanx (flexor pollicis brevis)			.5	5—10
	Opposition (opponens)	30+			
Wrist					10—14½

Tibial posterior nerve					
	Foot				
	Flexion	10		.5	10—10
	Flexion (plantar flexion)	10.8			10½—14
	Inversion (tibia posterior)	5.8			7—5
Peroneal nerve	Foot	10.5	9	.5	—5
	Extension				17—14
	Extension (dorsiflexion) (tibia anticus)	10.6	7		14—14
	Foot				
	Extension (dorsiflexion) (tibia anticus)				
	Everson (peroneus longus and brevis)				

Right handedness and left handedness had to be considered as well as the general muscular development in manual workers, in contrast to clerical workers.

It seemed impractical to compute a mean for each professional group and to select from the several means the correct standard for each examinee. We decided to determine the means (M) of the strength of various muscle groups, their standard deviations (SD) and standard errors (SE) in a hospital population which as a group did not show the fitness of combat soldiers. The random sample consisted of persons showing no nerve or muscle weakness and included manual and

clerical workers, as well as right handed and left handed persons (Table I).

To minimize the unavoidable variations, a standard method for measuring muscle function in patients with nerve injuries was developed. The method proved clinically adequate in use with more than 1,000 patients during a period of 2 years and the norms were found to be satisfactory and a few precautions were used. We believe that our results, as tabulated, permit a sufficiently accurate and rapid method for determination of the extent of motor nerve damage and of the progress of its recovery.

Fig. 2 Ulnar nerve.

Figs. 3-5 Standard position and fixation of hand and foot and direction of traction for measuring the strength of various characteristic movements. They are devised to prevent trick movements and minimize interference of auxiliary muscles. Presence or absence of contraction of the corresponding muscles has to be verified by inspection and palpation. The large figure indicates the mean strength of a hospital population, the small figures the range (± 1 SD) expressed in pounds (450 grams)

A METHOD FOR MEASURING MUSCLE POWER IN THE HAND AND IN THE FOOT

The apparatus used by us for these measurements are (1) a spring scale indicating up to 50 pounds and calibrated against a certified scale a small scale with a 64 ounce capacity is handy for measuring the first appearance of strength in hand and finger muscles (2) a wire about $\frac{3}{16}$ inch thick and about 4 inches long one end of which is bent to hook into a ring of the scale, the other end bent into an open loop of about $1\frac{3}{4}$ inch diameter covered with a rubber tube (3) the same type of wire formed into an isosceles triangle of 4 inches length the base of which is padded with rubber the opposite tip bent to hook into the scale, (4) a thin metal plate about 4 inches long and 1 inch wide with a hole in one end for the scale. The plate is

wrapped in tape to give a good grip These fittings are shown in Figures 1 and 2

Directions The patient is informed of the principles of the method and admonished energetically and repeatedly during the entire examination to apply all possible force in resisting the pull of the scale. Hand fingers or leg have to be fixed by the examiner in such a manner that the patient is prevented from pulling with arm and leg instead of using the muscle groups under scrutiny Figures 2 to 4 show the procedure in testing the forearm hand or finger muscles. In the foot plantar and dorsal flexion of foot and toes eversion and inversion of the foot are tested (Fig 5) This same method could be applied for measuring other muscle groups in the arm and leg

It is important to hold hand fingers and foot respectively, exactly as indicated and to

Fig 3 Median nerve.

exercise traction in the given direction. Patients develop unconsciously innumerable trick movements and learn to use auxiliary muscles. The positions of extremities hook and scale have been so chosen as to exclude— as far as possible—such undesirable errors, as the contraction of the finger extensors in e.g. the contraction of the index or little fingers. Nevertheless, inspection and palpation of the muscles or muscle groups under scrutiny should not be omitted.

The results were recorded, either directly in pounds or in percentage of the normal, depending on the purpose for which they were used (Figs. 6 to 8). The large figure (M) was used to compute the percentage of deviation from the norm. The range (small figures, $\pm 2SD$) gives a general idea of what strength can be expected in a certain movement. The pounds given on Figures 2 to 5 are slightly at variance with those of Table I. They are rounded to a quarter of a pound in contrast to the calculated values of Table I.

The unit of measurement was noted on each chart with the date and name of the patient and the examiner. We found special remarks sometimes useful, e.g. that the patient did or did not apply maximal force, that he seemed to be in good or poor condition that it was a very hot day etc.

Figure 6 gives an example of loss and gradual improvement of function following severance and suture of the median nerve at the wrist. There was no function in any of the hand muscles when first examined 3 months after suture of the nerve. In addition, there was a mild weakness from disuse in the ulnar musculature. At the time of the last examination 14 months after operation all intrinsic muscles innervated by the median nerve were active with the exception of the abductor pollicis brevis which frequently fails to return. The end phalanx of the index finger could not be moved because of partial ankylosis. The ulnar innervated muscles had returned to almost normal strength.

which does not permit total removal of the peritoneal sac must be viewed with misgivings as to its adequacy. The inferior or femoral approach does not permit visualization of any structure above or internal to the inguinal ligament and therefore it precludes total extirpation of the sac. This route only permits ligation of the femoral variant at its juncture with the parent sac. Further it is not possible to determine the presence or absence of other locules of the sac or to appraise the integrity of the structures of the floor of the canal from this approach. Apropos, I should like to point out that ligation of the peritoneal locule at the level of the femoral ring is comparable to obliteration of the funicular component of the sac at the external or aponeurotic ring, a procedure which has been abandoned as inadequate since the exposure of the inguinal canal by Championniere in 1881. The technique of removal of the sac should follow a well established plan (Fig 1). The femoral variant should first be unguinalized after which it is handled as in any inguinal hernia (Fig 2). Should the femoral locule arise from the direct component of the sac, a frequent finding, an intermediary step of indirectizing the direct variant (Fig 3) will be necessary before complete removal of the sac.

2 *Insufficiency of the inguinal ligament* Structural inadequacy of the inguinal ligament should be suspected in all recurrent hernias and in those primary hernias exhibiting diffuse weakness of the wall. The presence of a defect in the floor which has no clearly definable fascial boundary further enhances this suspicion. However, conclusive evidence of ligamentous insufficiency may not be recognizable without exposure by careful dissection of each parietal stratum. After mobilization of these structures, determination of the tensile strength of the inguinal ligament and that of the related fascial planes is simplified. Sharing in importance with the integrity of this ligament is the relative fixity of its inferior margin which can be demonstrated by downward pressure directed from within or by making traction on the ligament outward. If either of these maneuvers produce widening of the interligamentous or subinguinal space particularly if there is concomitant anterior curving or convexity of its inferior margin the ligament is considered inadequate for reparative purposes. Often the diffuse bulging encountered in the presence of such coexisting structural deficiency is frequently mistaken for a femoral hernia.

To overcome the deficiency of the inguinal ligament 3 alternatives have been proposed (1) substitution of Cooper's ligament, (2) running a

suture, preferably fascial, through the inferior margin of the inguinal ligament and through Cooper's ligament, which steadies the former (the criterion for this maneuver is a ligament of normal density with no attenuation but possessing undue laxity) and (3) when there is practically total destruction of the inguinal ligament, replacement with a pedicled fascial graft.

Lotheissen's ingenious idea of substituting Cooper's ligament for the inguinal ligament for anchorage of the parietal wall has received more sustained favorable reception than either of the other technical procedures. Among the chief proponents of this procedure are Dickson, Fallis McClure, and Harkins and Swenson. However neither Lotheissen nor his contemporary Narath made any attempt to implement the repair by closing the interligamentous triangular space. In those cases in which only ligamentous laxity is present, Moschcowitz, and later Seelig and Tuholske advocated suturing the inferior margin of the inguinal ligament to Cooper's ligament. Payne employs a pedicled suture from the external aponeurosis for the closure of this space. However, this maneuver does not obviate the necessity of complementary repair of the floor by Bassini's method or one of its modifications. Therefore Cooper's ligament plays only an auxiliary role in the Moschcowitz technique. Ordinarily one should expect long standing, massive hernias to predispose to weakness of the inguinal ligament in contrast to a higher incidence of friability or fragmentation of the ligament in cases of recurrent hernias.

Methods of replacing Poupart's ligament have been described by Wilmoth Cowell, and Turner which have definitive variations but are fundamentally alike. They consist in transplanting a pedicled fascial flap from the anterior surface of the tensor fascia femoris muscle and fixing its inferior margin to Cooper's ligament. Strategically it would seem that in rebuilding the floor of the canal this maneuver offers no advantages and is technically more difficult than transfixion of all the parietal layers jointly to Cooper's ligament. The latter reparative innovation has its counterpart in Joyce's method differing only in substituting Cooper's ligament for the inguinal ligament. Wangenstein's iliotibial tract transplantation is indicated when inadequacy of the fascia transversalis is also present.

3 *Marked laxity of the parietal strata.* Initially the weakness of the floor of the canal is congenital arising from maldevelopment and maldescent of the gubernacular cord and from anomalies occurring during the process of differentiation of the

Fig 4 Radial nerve.

Figures 7 and 8 record the course of an ulnar nerve paralysis and lysis in the middle of the forearm. Figure 7 shows the increasing strength in pounds. Figure 8 in percentage of the norm. The last illustration of this figure indicates practically full return of function in all muscles with the exception of the abductor indicis. This muscle was seldom used in the patient's work. The abductors of the first and second fingers seem to be innervated by a twig from the median nerve.

This form of recording gives at any time an immediate survey of the progress of recovery following a nerve lesion and a survey of the functional deficit in percentage of the norm.

DETERMINATION OF RELIABILITY OF THE METHOD

Controls It remained to demonstrate what degree of reliability could be expected from measuring the strength of voluntary muscle contractions by means of the spring scale with the described precautions. A comparative study was made for this purpose on the abductor digiti quinti muscle in 76 patients with ulnar nerve lesions. The strength of this muscle and its gradual increase over a longer period of time was determined in sequential examinations and expressed in percentage of the normal. Simultaneously the electromotive force (EMF) generated by this muscle on maximal electrical stimulation of the ul-

Fig. 5. Posterior tibial and peroneal nerves.

nar nerve (amplitude of electromyogram) was measured in millivolts and expressed in percentage of the value obtained on the normal side of the patient. This procedure may be called an objective method. The values obtained by the two methods of examination were plotted against each other. The scatter diagram (Fig. 9) shows a high degree of relationship ($r = +0.79$) between (1) the EMF on maximal nerve stimulation and (2) the strength of voluntary contraction, both expressed as percentage of normal, in the same muscle at the same time. A standard error of 0.04 indicates that r' departed highly significantly from zero.

We were interested in this context in the reliability of the percentage values of voluntary strength. Strength was therefore chosen as the dependent variable (Y). The standard error of estimate in Y (\hat{Y}) was found to be 12.7 per cent. RR is the least squares regression line.¹ The bands of normality on each side, $\pm 2\sigma Y$ (25.4%) are shown as dotted lines. This permits one to estimate or predict the value of strength (\hat{Y}) if the EMF (X) is known. Insert the determined value of EMF in per cent of the normal on the abscissa, follow this line up to the point where it bisects

The meaning of the Y intercept (OR) will be discussed in another context.

Fig 6.

Fig 7

Fig 8.

Fig. 6. Three stages of improving muscle strength in a patient with median nerve interruption and suture above the wrist. From left to right, 3.6 and 14 months after suture. The first picture explains to which motions the standard location of numbers refers. Dotted numbers, originally written in red, indicate deficient strength. Strength in pounds (450 gm.)

the regression line and read the predicted value of strength in per cent of the normal on the ordinate.

The 0.99 fiducial limits of the coefficient of correlation are between 0.61 and 0.89. This means that taking an indefinitely large

number of persons homozygous with the 76 actually examined it is highly likely that the coefficient of correlation will fall within the limits of 0.61 and 0.89.

The scatter diagram shows that out of 76 or approximately 95%, of all persons falling with

Fig. 9. Scatter diagram of strength in the abductor digiti quinti, measured by means of a spring scale and expressed in percentage of the normal, plotted against the electromotive force generated by the same muscle on maximal stimulation of ulnar nerve at elbow measured in mV (amplitude of electromyogram) and expressed in per cent of the corresponding value in the patient's normal arm. Full dots, nerve sutures. Open rings, neurolysis. R.R., fitted regression line with the bands of normality on each side. $\pm 2\%Y$, standard error of estimate in Y .

in the limits of $RR \pm 2\%Y$. This percentage corresponds very closely with the results expected when a straight regression line is appropriate to the data and when the points are normally distributed around the line. We may therefore use this line and the limits of $RR \pm 2\%Y$ as the normal region. If a point falls outside these limits, it is likely that there is something extraordinary about the patient. If the point lies above the upper limit we have no interest in the extraordinary cause in this paper. If it lies below the lower limit it is legitimate to take the result as an indication of inadequate voluntary contraction. The method here developed seems pertinent to the problem but more reliable values for $RR \pm 2\%Y$ could be obtained from enlarging the sample.

The results of the spring scale method may therefore, be called reasonably reliable, reproducible and comparable. Furthermore, Figure 9 gives a reasonable basis of action

until larger studies are made. The measurements provide a good record of individual return of muscle strength from zero to one hundred per cent, or wherever the curve levels off.

Limitations. The values obtained with this method are approximations. Differences of less than one half pound should be considered—as far as our experience goes—within the range of the experimental error in the small hand muscles, whereas differences of 1 or 2 pounds may be neglected in the stronger muscle groups. Hence, not much change could be expected from examinations at short intervals in the case of a regenerating nerve. Our routine examinations were spaced 2 to 3 months apart beginning as soon as the first signs of returning function were observed.

SUMMARY

A standardized method of measuring the function of various muscle groups in hand, fingers, foot and toes by means of a spring

ACUTE PANCREATITIS

II An Experimental Study with Special Reference to X ray Therapy

TAGUE C. CHISHOLM M.D. Minneapolis, Minnesota, and ROY E. SEIBEL, M.D.
Buffalo, New York

IT is now commonly recognized that the method of choice for treating acute non suppurative parotitis is with roentgen rays. About 1938 Morton and his co-workers in Rochester New York were struck by the interesting analogy between the parotid gland and the pancreas both of these glands were of the serous type and blood amylase levels were elevated with disturbances of either. In 1940 Morton and Widger encouraged by their early experiences with the roentgen treatment of acute pancreatitis, published their first clinical report. In 1945 we reviewed the clinical and pathological records of the 8 cases of acute pancreatitis treated by roentgen therapy in the Peter Bent Brigham Hospital in Boston together with the 13 cases then reported in the literature.⁽¹⁾ The series was too small and the available data too scanty to draw any conclusions. In an endeavor to place the x ray treatment of acute pancreatitis on a factual, rather than an empirical foundation the following experimental studies were undertaken.

METHOD

In order to create acute pancreatitis in our investigation we adopted the method described by Rich and Duff in 1936 in their classical study on the pathology of experimental pancreatitis in dogs. Under nembutal anesthesia² the second portion of the duodenum was opened. The duct of Santorini was cannulated with a blunt No. 25 needle and bile, freshly aspirated from the gall bladder was injected into the pancreas. When less than 2 cubic centimeters of bile was slowly injected into 16 kilogram dogs at a pressure lower than 18 centimeters of water the ductal tree of the pan-

creas was filled but not ruptured. In a matter of a few minutes acute edema of the pancreas immediately developed while the organ was under direct vision (Fig. 1). The lobules became widely separated by a transparent transudate which microscopically showed a few extravasated leucocytes but primarily an interacinar edema. When 2 to 10 cubic centimeters of bile was as rapidly injected into dogs at a pressure over 18 centimeters of water the ductal tree of the pancreas was ruptured, the immediately visible interlobular edema became bile tinged (Fig. 2) and in a matter of a few minutes small petechiae appeared in the acinar substance. Microscopically the pancreas at this time displayed large numbers of extravasated erythrocytes leucocytes, fibrous, and granular debris. Several hours after the injection of bile this type of pancreas (Fig. 3) showed numerous yellow plaques of fat necrosis, both in the substance of the pancreas and on the omentum, mesentery and peritoneal surfaces.

RESULTS

Figure 4 shows the curves of serum amylase levels from 10 acute experiments over a 12 hour period. After the induction of acute pancreatitis, blood samples were periodically taken until the dogs were sacrificed. The solid lines represent steadily rising serum amylase levels in dogs which displayed severe necrosis at autopsy. The broken lines represent less acute rises in serum amylase levels in dogs which showed only edema at autopsy. The former received 2 to 10 cubic centimeters of bile under great pressure, thus rupturing the ductal tree. The latter received less than 2 cubic centimeters of bile under mild pressure and showed no extravasation of bile outside the pancreatic ducts. In the former blood amylase levels continued to rise until the end of the 12 hour period of observation, while in the latter during the same interval serum

From the departments of surgery and radiology, Peter Bent Brigham Hospital, and from the Laboratory for Surgical Research, Harvard Medical School. Dr. Chisholm, Arthur Tracy Cabot Fellow in the Laboratory for Surgical Research, Dr. Seibel, Resident in Radiology, Peter Bent Brigham Hospital.

Dosemge: 2 milligrams per kilogram administered intravenously.

amylase was either approaching or had returned to normal levels.

Figure 5 shows the curves of serum amylase levels from 10 acute experiments followed over a 7 day period. These operations were done with aseptic precautions and blood sampling was conducted periodically until the dogs were sacrificed. Again the solid lines represent animals receiving injections of large amounts of bile under increased pressure; these dogs uniformly sustained quite high serum amylase levels which only slowly fell toward normal. At autopsy they showed varying stages of subsiding pancreatic necrosis. The broken lines represent dogs receiving injections of less than 2 cubic centimeters of bile under low pressure in which amylase levels rose to less high levels returned to normal sooner than in the companion series and at necropsy showed only the end results of an acute edema of the pancreas.

The next objective of the study was to ascertain what was the response of the normal pancreas to x ray therapy as reflected by alterations in the blood amylase levels. Figure 6

Fig. 1. Acute edema of the pancreas a few minutes after gentle retrograde injection of bile into the duct of Santorini.

indicates the response in 6 dogs to a single treatment of 90 r each (represented by the solid lines) and in 5 dogs to 200 r each (represented by the broken lines). These doses were delivered over a 15 square centimeter area of the epigastrium with a skin target distance of 50 centimeters, a peak kilovoltage of 200 a

filter of 1 millimeter of aluminum and $\frac{1}{4}$ millimeter of copper and 18 milliamperes. Of the series receiving only 90 r all had direct drops in serum amylase levels over a 12 hour period with return to or toward normal in 2 to 5 days. At the time of autopsy every pancreas of this series showed subsiding hyperemia but no edema or necrosis. Those dogs receiving 200 r in a single treatment displayed responses with great variations in the serum amylase titers. A few of the larger animals had drops corresponding to the series receiving 90 r. The smaller dogs, however, showed irregular rises in serum amylases and at autopsy had acute edema, petechiae and tiny foci of fat necrosis.

Since both Morton (2) and the radiology service in the Peter Bent Brigham Hospital had frequently employed a series of three consecutive treatments in their human patients with acute pancreatitis we investigated the serum amylase response of normal dogs to three consecutive exposures, 24 hours apart, of 90 r each. Figure 7 illustrates our findings in 5 dogs. There was a uniform depression of serum amylase levels after the first treatment but

with the second and third exposures a diffuse hyperemia with edema ensued. A few showed tiny foci of necrosis. All dogs in this series showed a steady rise in serum amylase levels after the second exposure to roentgen rays.

Finally we combined the aforescribed methods of first creating acute pancreatitis, and second immediately giving these subjects a single treatment of 90 r to the epigastrium. Seven dogs from this series are represented on Figure 8. All were given sufficiently large injections of bile to create pancreatic necrosis. Although more experiments must be carried out in this manner before irrefutable conclusions can be drawn nevertheless, it is of interest to note that in not a single instance did the serum amylase titers rise anywhere nearly as high as in the original series without x ray treatment. Yet at autopsy all of these dogs showed moderately severe pancreatic necrosis.

COMMENT

On the basis of the above described limited number of observations on experimentally induced acute pancreatitis with and without

Fig. 1. Mobilization and conversion of multifocal hernial sac. Sac showing indirect, direct, and femoral locules.

abdominal wall plate into three parallel superimposed muscles with their enveloping fascias. Intra-abdominal pressure, traction, gravity muscle contraction, and the expanding hernial mass play their respective roles in contributing to pressure atrophy and ultimate distortion of the parietal wall.

The decision of the adequacy of a structural variant may be an equivocal one. At times, laxity with diminished tone can be differentiated from attenuation of the tissues by stretching only by the experienced surgeon. Aside from embryonal weakness and parietal agenesis of the internal oblique muscle, the attenuation of the wall is due chiefly to the progressive enlargement and piston ing action of the hernial mass. From a reparative standpoint the mural deficiency is more important than the type of hernia present. For instance, in large indirect hernias the epigastric vessels are displaced medially and may rest under the rectus muscle. There is, of course, concomitant loss of the obliquity of the canal. With the exception of the position of the epigastric vessels, the parietal distortion is almost identical with that of large direct hernias which require similar corrective measures.

There is another anatomical type of hernia ordinarily not recognized in which the predominant feature is one of systemic mesoblastic weakness, most manifest in the groin. The coexisting sac is small, frequently without an ascertainable neck, and of secondary importance. This type is frequently found in the asthenic individual presenting subclinical myasthenia. It is conceivable that the individuals in whom the angle of divergence of the anterior abdominal wall and the pubic bone is greater and in whom, therefore, the infundibuliform space is larger would be predisposed to hernia in the inguinal sector (Morgan and Anson). Individuals of this type are frequently rejected by the industrial physician. Surgical measures are required principally to reinforce and make taut the composite atonic wall. In this group the ablation of the sac and closure of the hernial defect will not suffice as it does not correct the generalized laxity of the lower anterior abdominal wall. Since Poupart's ligament participates in the coexisting weakness by reason of its derivation from the external aponeurosis, it should not be used for anchorage but by substitution of Cooper's ligament, which is strong and unyielding, a taut, resistant wall is attained. The repair may be implemented by a fascial suture spanning the interligamentous space, which will simultaneously correct the laxity of the inguinal ligament and further add to the general security of the wall.

4. *Arborization of the sac* Total excision of the sac and its locules is universally accepted as the first cardinal step in the modern repair of hernia. This prerequisite in the surgical treatment of hernia has progressed through many evolutionary phases from ligation of the sac at the external ring ligation in the canal, and, finally after opening of the external aponeurosis, to ligation at the abdominal level of the internal ring. The recognition of the frequency of the polylocular sac has made it obligatory to explore digitally the interior of every sac. Statistical studies of recurrent hernias (5, 6, 11, 21, 28) have shown that overlooked locules and, consequently failure to remove them at the initial repair is a more frequent cause of relapse than is generally believed. Similarly the shortening of the operating time by transecting the scrotal sac without freeing its fundus, as proposed by Stoker and O'Hara, has been abandoned because of incompleteness and because of the occasional complicating hydrocele of the sacular remnant. Incidentally much collateral information may be gained regarding the dynamics of the hernia by understanding the anatomical anomalies predisposing to the development of the devious routes of the sacular variants.

x ray treatment it appears warranted to conclude that too large a dose of roentgen rays may well defeat the purpose for which it is administered i.e. to inhibit enzyme production in the already damaged pancreas. Further more it is suggested by the aforescribed studies that repeated serial exposures of x rays to the pancreas may well have a cumulative effect as deleterious as an initial heavy exposure. And finally that an appropriately small single dose of roentgen rays administered to dogs having experimentally induced pancreatic necrosis appears to inhibit amylase enzyme production with minimization of pancreatic tissue destruction. The application of these observations to the roentgen treatment of acute pancreatitis in humans is clearly suggested.

SUMMARY

1 Observations are reported on the pattern of serum amylase curves in dogs with experi-

mentally induced acute pancreatic edema and acute pancreatic necrosis.

2 Similar observations are reported following periods of x ray treatment to the normal pancreas.

3 Other observations are reported on the behavior of the serum amylase curves in dogs receiving acute experimental pancreatic necrosis followed immediately by a single x ray treatment of 90 r.

4 And finally the application of these observations to the roentgen treatment of acute pancreatitis in humans is discussed.

FUTURE SURGEONS

FOR a hundred and fifty years in this country surgical training was for the most part informal and vague. Over the past five decades various patterns that one might follow to become a surgeon have evolved. In the last twenty years these have become more distinct, with the result that surgical training has been defined and standards established. He who embarks on a career of surgery is confronted with a protracted period of training after graduation from medical school. Heretofore, the surgeon after a long period of residency or apprenticeship with little or no income could expect to receive in a relatively short earning period and by the time he had reached the age when he could no longer work compensation that would equal the total income of his medical confreres. Thus his family although often an addition of his later life had security and provision for education. Today taxes and the trend of fees make the annual net income of the surgeon

during his most active periods of practice so limited that he cannot set aside appreciable savings that will compensate for the long lean years of preparation or provide for his old age.

As medical school graduates continue to embark on surgical careers with an eye to their immediate and future livelihood, they will require and seek a reasonable subsidy during this training period. If incomes are to be limited, a subsidy should be available during the many years of preparation which are required. The cost may be borne by the hospital, the community or the state. Surgery and its specialties more than other divisions of medicine, demands intensive and prolonged training. The present generation has seen those who are now its leaders of surgery struggle through such training. The merit of the system for a few in the past is undeniable, but for the majority both for the present and the future its applicability is questionable.

In this present period after the second World War it appears that many changes may be anticipated. The continuity of trends prior to the war were interrupted and now after the many surgeons who were in the service have returned, new problems become evident. These changes involve all of medicine. There is a strong trend toward hospital practice. Almost every community is planning an increase in the number of its hospital beds and those up to now without hospital facilities are contemplating building them. In the future, a greater number of surgeons will be required. The actual standards of surgery will depend upon the training these surgeons of the future receive.

The emphasis in the building of hospitals has been on the physical plant and equipment.

This is important but more important is the hospital staff which should be continually improved. The quality of the work done by a staff is dependent on the training of its members. There are many large hospitals in the country that have competent and well trained men who take excellent care of patients but who contribute little or nothing to the instruction of those in training. This is particularly true in municipal county and private hospitals located in towns and cities without medical schools. The community should be concerned with the cost of the staff as well as the building and its equipment. A subsidy is needed to pay certain members of the senior staff to carry out a training program and to provide the surgeon in training a sufficient income so that he can maintain a social position equal to that of his peers in other professions.

In effect, it is proposed that all hospitals become teaching institutions, that they serve as the medical centers of the community. Today it is unfortunately true that some small hospitals so far as surgery is concerned may be a liability to a community rather than an asset. Surgeons should be interested in a policy that provides for hospitals of sufficient size properly equipped and staffed to do adequate and sound surgery. The resident system of training in surgery as now employed in many of the university medical centers modified to meet local circumstances might well be utilized throughout the country to the advantage of the future surgeons and their patients. Such a plan should materially increase the number of properly trained surgeons who will be needed in the future and of equal importance it will stimulate the surgeons associated with these

hospitals to keep abreast of advances and create channels through which new information can be easily circulated. Benefits that may accrue will be of greatest value to the citizens of the community in which these hospitals function.

The various insurance schemes for hospitalization have gained great popularity over the last few years and the trend continues. These programs in a period of economic prosperity have been accompanied by a decrease in the number of patients occupying teaching beds. Many hospitals dependent on endowment for support have had a reduction in income and an increase in operational expense. Many hospitals consequently have embraced the insurance plans. As a result ward services have been curtailed and clinical material for training purposes has been reduced. This is unfortunate because patients are benefited when properly used for teaching purposes. The majority of well staffed hospitals could evolve a plan whereby patients who are insured would be taken care of by the senior and resident staffs and at the same time be used for teaching purposes.

Surgeons should understand the problems that confront the medical school graduate as he views surgery as a possible career. The value of a long thorough training in properly staffed and equipped hospitals with adequate clinical material is evident to surgeons but requires emphasis to the profession and laity. The cost of training professional personnel in a hospital should be looked upon as one of the best long time investments that the community which supports that hospital can make.

VIENNA 1947

ALEXANDER BRUNSCHWIG M.D. F.A.C.S., New York, New York

DURING the past summer a mission was sent to Austria by the Unitarian Service Committee under auspices of the World Health Organization (Interim Committee). There were eight members from the United States representing physiology (Visher University of Minnesota), pharmacology (Cattell Cornell), cancer research (Bittner University of Minnesota), internal medicine (Chester Jones Massachusetts General Hospital and Harvard), psychiatry (Wortis, New York University), general surgery (Brunschwig Memorial Hospital and Cornell), neurosurgery (Joseph Evans, University of Cincinnati), anesthesiology (Stewart Cullen Iowa State University College of Medicine). There were two Swiss members, Prof. Alfredo Vannotti (Lausanne) internal medicine and Prof. Herman Mosser (Zurich) hygiene and public health. The purpose of the mission was to acquaint the Austrian medical profession with advances in various fields that had been made in America and Switzerland since 1939 when scientific communication between Austria and the outside world was almost completely cut off and to receive information regarding progress made in the Austrian clinics during this period. This plan was carried out by means of lectures, informal conferences, ward rounds, and operative work on the part of the mission members.

Because of the large number of American surgeons who attended for varying periods the clinics in Austria, especially Vienna, the writer summarizes in the following paragraphs the situation in Austria as observed during the aforementioned voyage.

The Allgemeines Krankenhaus is essentially undamaged and the general activity is quite similar to what was observed by the writer in 1931. The first surgical clinic is headed by Professor Schoenbauer who is active in general surgery and does the neurosurgery for this and other hospitals as

well. The second surgical clinic is headed by Professor Wolfgang Denk, and is traditionally "The Clinic of Billroth." The author had the privilege of examining the preserved specimen of Billroth's first pylorotomy for carcinoma. Professor Denk is especially interested in thoracic surgery and has recently begun to do total pneumonectomies and transthoracic gastroesophagectomies. He is also Dean of the Medical Faculty. Professor Finsterer is working as hard as ever and continues to direct his *abteilung*. His seventieth birthday was recently celebrated by a public ceremony at the hospital. Professor Kahr is head of the first gynecological clinic (Wertheim's clinic) and Professor Antoine is head of the second gynecological clinic (Schauta's clinic). Dr. Schoenbauer is also head of the Institute of Medical History and during the war period his book concerning the history of the Medical Faculty of Vienna was published. This is a beautifully written and illustrated book which will prove a standard reference in years to come.

The shortage of catgut is so acute that silk and linen suture material are used almost exclusively. The supply of rubber gloves is also short and this necessitates the use of cotton gloves in some clinics no gloves are used. The author had the experience quite arresting for an American, of operating without gloves and once over the initial surprise it afforded the impression that dexterity was facilitated. There is no shortage of surgical instruments in the operating rooms.

Blood banks are nonexistent. Transfusions, when given (which appears to be not very often) are administered by the direct method. One or two donors are held in a room adjacent to the operating room and lie down on stretchers when utilized. Blood is drawn into a paraffinized Kump-ton tube and brought quickly to the patient; the blood is run in by means of a large cannula previously inserted by cutting down upon a large vein.

Little stress is placed upon postoperative fluid balance and in one large clinic there were no out-

From the Memorial Hospital for the Treatment of Cancer and Allied Diseases, New York.

fits for intravenous infusion by venipuncture. When such measures were to be carried out, a large cannula was inserted into a vein by the cut down method. Sterile physiologic saline solution was generally available but dextrose solutions were not available due to the shortage of sugar. Vitamins C and K are available in limited quantities. No records of daily urine excretion are kept routinely. Continuous gastric aspirations by means of Levine tubes and suction does not appear to be practiced anywhere in Austria. Early ambulation is carried out irregularly.

Sulfa drugs are plentiful. Penicillin is obtainable in only limited quantities and often when it is requested there must be a bacteriological study to prove that the infective organisms are penicillin sensitive. Streptomycin is not available. Opium and its derivatives are not plentiful and indeed in some clinics were not available at all. Small quantities of thioracil have been provided and a few patients have been treated with it.

The operative work observed was very high grade for the routine procedures. Few or none of the newer operations have been attempted. Total pneumonectomy has not been performed in Austria more than possibly six times, probably fewer transthoracic cardioesophagectomies have been done. No pancreatoduodenectomies have been performed. The heavy metal intramedullary pin (Kutcher pin) is frequently used in fractures of the femur and there appears to be satisfaction with the results. Prefrontal lobotomy has not been carried out. Irradiation therapy for carcinoma of the cervix has never been as extensively employed as elsewhere. Patients with Stages I and II (and often III) receive either the radical vaginal hysterectomy (Schauta) or the radical abdominal hysterectomy (Wertheim). The latter is carried out according to the original operation in which excision of parametrial tissue is emphasized but no attempt is made to remove extensively the lymph nodes along the great vessels of the pelvic wall. The wide use of the term "Wertheim operation" in the United States to indicate a very radical hysterectomy should be abandoned as Wertheim did not conceive of the operation that is inferred by American surgeons and gynecologists (radical node resections). It was stated that the immediate surgical mortality is about 5 per cent for the Wertheim operation. No recent follow-up studies on results are available.

Peptic ulcer when first encountered is treated medically but this regimen does not appear to be as rigid and vigorous as conceived by internists in the United States. When this has failed resection is done. Duodenal ulcers are managed by

Billroth II Pólya, or Finsterer operations gastric ulcers by Billroth I. The latter is performed with radical gastrectomy and the surgeons appear satisfied with it claiming few recurrences. In some instances, after gastrectomy calomel tablets were placed in the opened small bowel to insure early evacuation of stool and reduce the incidence of distention and paralytic ileus.

Neoplasms of the colon are treated in several ways and there is a marked tendency for multiple stage excisions due to lack of penicillin, and poor nutritional state of these patients when they are admitted for treatment. Much of the operative work is done under local or spinal anesthesia. General anesthesia is given by junior assistants who do not remain very long on this service. No physicians specialize in anesthesia but it is contemplated that specialization in the administering of anesthetics will develop.

Specialization in the various surgical fields is not extensively developed. While a rigid separation is made between gynecology and abdominal surgery, and the former is carried out by those who also are obstetricians, urology with its special instrumental armamentaria remains in the general surgical clinics and is the province of senior assistants who devote periods rotating on that service. Orthopedics likewise is not generally separated, although some surgeons are able to confine themselves to that field. Fresh fractures are taken care of in "traumatic stations" which are adjuncts to general surgical services. Neurosurgery has not developed as a special field nor has thoracic surgery. In Innsbruck (Prof. B. Breitenreiter) a surgeon limits his practice entirely to thoracic surgery (Dr. Kux) and another entirely to neurosurgery (Dr. Sargo). As mentioned these situations are unique in Austria.

Experimental laboratories in connection with the surgical clinics have not been developed and the surgeons have not become interested in some of the newer biochemical aspects of the surgical patient. For example the surgeon there is not familiar with the concept of plasma proteins and their implication for the surgical patient. Indeed, when the question was raised in connection with a patient undergoing an extensive operation no facility was available for making this determination—it had never been done before in surgical patients. This instance serves as a concrete example of the misfortune resulting when a group of surgeons are more or less completely cut off from international literature and personal exchange of ideas with men from other countries.

The writer performed transthoracic cardioesophagectomies upon 2 patients with cardioesopha-

REVIEWS OF NEW BOOKS

THE Danish Surgical Society conferred an award on Dr Aalkjaer in 1944 for the first publication of *Fluids, Electrolytes and Protein in Surgery*.¹ Recently this handbook of 150 pages has been revised and reprinted and now an excellent English translation is available.

Dr Aalkjaer has spent 10 years in developing a simple and practical routine for quantitative replacement of fluids, electrolytes and protein in his general surgical and urologic patients. This manual is a direct and complete description of the reasons for this program and of the means by which it is carried out. As the basis for this progressive work he has used the conclusions of more than 100 authors writing on these subjects at the present time. The comprehensiveness of his approach and the reduction of the many problems to simple terms and usages is to be highly commended.

The book is arranged in three parts: (1) the normal physiology of the electrolyte fluid-protein metabolism; (2) the pathologic physiology; (3) the clinical application. Under these headings the author describes first the fluid, electrolyte and protein requirements of the body and the essential laboratory determinations, then the physiologic changes that occur and finally the methods of quantitative correction of these changes. He clearly describes how quantitative replacement therapy can be used in a small hospital. Details are given as to adequate methods of laboratory analyses of protein, chloride and carbon dioxide, preparation of fluids, collection of blood and methods of administration. Excellent brief surveys on the differences of new and old bank blood, or the use of plasma in place of blood, and the use of new plasma substitutes such as dextran are given.

To facilitate replacement therapy in anemia, dehydration, acidosis, alkalosis and shock the author has reproduced many charts of other investigators, for example, Gamble, Van Slyke, Collier and Maddock, and also from his own work. Case reports of interest in fluid or electrolyte or protein problems are frequently given with the addition of a simple chart showing daily laboratory and urine tests along with total output and total input. Interesting observations are made on uremia being resistant to treatment before the carbon dioxide is corrected and on loss of fluid from the intestine.

The author assumes some familiarity on the part of the reader with the essentials of electrolyte balance and gives abbreviated formulas for conversion and for diagrams. If the reader is not familiar with the constant acid base equation in the body, he is stim-

ulated to study the subject to determine the source of the figures. In one instance the author has used a chart and formula for the administration of sodium chloride after Collier and Maddock which has since been refuted by these authors. An actual calculation of the milliequivalents of chloride to be replaced on the basis of the blood plasma deficit and the body weight is a safer approach in this instance.

Dr Aalkjaer has made a fine contribution to surgery in this monograph. In addition to the practitioner every teacher of surgery in medical schools or hospitals should read this manual as a possible reference book for his students.

DONALD C. BALFOUR, JR.

IT is probable that relatively few physicians actively engaged in the practice of medicine today have the slightest conception of the travail and racking disappointments endured by our forefathers in attempting to systematize and organize the practice of medicine in the United States. The progress of medical development has lagged at times but it has always gone forward. Unfortunately there are always some physicians who are more concerned with their personal welfare and progress than that of the profession as an organized entity. Nothing in organized medicine is durable or stable unless it unselfishly serves the welfare of mankind. As conditions of life change so must the concepts of organized medicine change, always keeping in the foreground the one salient objective—the preservation and restitution of health. There may be honest differences of opinion as to procedure. One man may be looking and planning far ahead of his time and his intellectual foresight may be extremely acute. Too frequently such an individual is ridiculed and his advice rebuffed. Thus is one of the unjust penalties that has been suffered by many not only in the medical profession but in all scientific fields. The harmonious organization of the medical profession in the United States has been a tremendous task but it was no greater than the wisdom and efforts expended by the men who brought it about. This fact is well illustrated in *A History of the American Medical Association* by Fishbein.²

For interesting reading this book can be recommended heartily. Organized medicine may be just a bit behind the advance line of scientific medicine yet it has followed medical progress very closely. Of necessity this must be so. It is just to say that organized medicine has never as a body strayed from a true scientific course as so many other organizations have. It has in the past definitely urged reforms and fought for principles deemed necessary to protect

¹ FLUIDS, ELECTROLYTES AND PROTEIN IN SURGERY; ACIDOSIS, ALKALOSIS, DEHYDRATION, CATABOLISM, PROTEIN DEFICIENCY, ANEMIA, SHOCK. By V. Aalkjaer, M.D. (Translated by Miss Annie L. Famboll, M.A.) Copenhagen: Einar Munksgaard, 1947.

² A HISTORY OF THE AMERICAN MEDICAL ASSOCIATION, 1827 to 1947. By Morris Fishbein, M.D. Philadelphia and London: W. B. Saunders Co., 1947.

human welfare. Repeatedly its demands have been carried to the door of the president of the United States. One cannot escape the question as to whether today the association is as virile and aggressive as it was 50 or more years ago. As early as 1852 the American Medical Association brought to light conditions to which steerage passengers in ocean steamships were subjected and demanded reforms. In 1854 dietary deficiencies in children were studied and an attempt made to correct conditions. In 1884 organized medicine was confronted by antivivisectionists and the situation was met as well as it is today if not better. The first concrete attempt to curtail 4th of July accidents was made by the American Medical Association in 1903. It is a tragedy that the public has insisted on allowing ruthless destruction and maiming of our youth for sport, this in spite of years of admonishment.

Many of our medical forefathers considered honesty and gentle conduct an essential for the practitioner of medicine. In 1903 definite action was taken against fee splitting and solicitation of votes by one seeking office in the society. For many years the code of ethics was of supreme importance and much time was devoted to its development. We still must recognize that honesty in medicine is as important, if not more so than unusual skill and learning.

This volume of approximately 1200 pages is divided into a number of sections. By way of introduction there is incorporated a very interesting sketch of the life of Nathan Smith Davis the father of the American Medical Association. The first section gives data on the formation of the American Medical Association and the high lights of the numerous annual meetings. A section is devoted to the recipients of the distinguished service medal, one to biographies of the 111 president of the association, one to the councils and bureaus of the association and one to publications of the association.

This book not only affords interesting reading but it is a storehouse of information on medical progress and organization. It depicts the characteristics of many men who for at least another century will be revered and honored as the fathers of American medicine.

JOHN A. WOLFE

FIRST published in 1834, *Pye's Surgical Handicraft* has progressed with the growth of medicine and surgery through 15 editions. The current edition by 44 contributors in England and Scotland and edited by Hamilton Bailey remains faithful to the endeavors of the original author. It continues to describe the details of surgical work as they appear from the viewpoint of the house surgeon and interne who must ever strive to become a skilled handicraftsman.

The volume is replete with excellent illustrations many in full colors and some tinted in part. Unfortunately the selection of colored plates seems to have

been somewhat haphazard rather than to fill a particular need. However on the whole, the presentation of technical procedures is extremely informative and affords an unusual clarity of explanation.

Much of the book is devoted to the hospital or surgical problems which are taken up in a regional manner. There is a slight but understandable lag behind the progress in certain fields, notably in the brief and inadequate references to chemotherapeutic agents and anticonvulsants. Such chapters on the treatment of burns and the management of surgical thoracic cases have not kept pace with advances in these fields.

The American reader may encounter a few familiar terms among the medications and drugs but this is not conspicuous and in no way detracts from the excellence of the text. It is packed with abundance of practical points which will prove of great value to the surgical resident, interne, student, and to the practicing surgeon as well. The reviewer recommends this volume most highly.

EDWARD W. GALT

LIKE the modern hotel with a bath in every room, *Surface and Radiological Anatomy* continues to improve. This second edition has been necessary to enlarge the text to replace all of the earlier skiagrams, and provide surface illustrations. It is prepared for the student who in his dissections, will find it useful to consult knowledge of surface identification with the parts which he is investigating. This splendidly illustrated book will also serve radiological and surgical fellows preparing for board examinations.

Far more radiological fundamentals could be added to advantage. Particularly commendable are surface identification of blood vessels, nerves, lymph glands and vessels. The book is obviously written for students and for those who would refresh their memories later in practice. It is worthy of a large contribution than it will achieve.

EDWARD H. SEXTON

THE little book of 120 pages *A Short Handbook of Practical Anesthetics* by Noel Parry-Pool is written in refreshingly frank style characteristic of many British writers. It outlines the author's personal experiences and the lessons learned between 1930 and 1945 both in civilian and military practice. It will be found of real value by resident-anesthetists and thoroughly experienced anesthetists will appreciate many of his points of view.

An interesting foreword, written by Mr. Cecil G. Wakeley Consulting Surgeon to the Royal Navy.

MESSAGE AND RADIOLOGICAL ANATOMY FOR STUDENTS AND CLINICAL PRACTITIONERS. By A. B. Appleton, W. J. Hamilton, and C. C. Thompson, and edited by A. B. Appleton, M.B., B.S. (Cambridge), F.R.C.S. (Edinburgh), M.D. (D.C.), F.R.S.E., and O. Isaac, M.D., B.S. (Edinburgh), M.D. (D.C.). Baltimore, The Williams & Wilkins Co., 1944.

A SHORT HANDBOOK OF PRACTICAL ANESTHETICS. By Noel Parry-Pool, M.B., B.S., L.R.C.P., D.A. (R.C.S.). With foreword by Cecil G. Wakeley, C.B., F.R.C.S. John Wright & Sons, Ltd., London (London: Simpkin, Marshall, 1944).

PYE'S SURGICAL HANDICRAFT: A MANUAL OF SURGICAL MANIPULATION. MINOR SURGERY AND OTHER MATTERS CONNECTED WITH THE WORK OF SURGICAL DISSECTORS, HOUSE SURGEONS, AND PRACTITIONERS. Edited by Hamilton Bailey, F.R.C.S. (Edinburgh). 15th ed. Baltimore: The Williams & Wilkins Co., 1947.

Fig. 2. Mobilization and conversion of multifocal hernial sac. Femoral locule inguinalized.

5 *Multiple interfascicular defects with fascial incompetency* One explanation offered for diverticular herniation is the sparsity of widely separated fasciculi of the internal oblique muscle and the coexisting interfascicular spaces in the middle sponenrotic stratum. If the spaces are large and the investing fascia bridging them velamentous, they become potential exits through which a hernia may protrude. Subperitoneal adipose tissue or a locule arising from the direct component of the sac may force itself through these vulnerable areas. Since diverticular hernias are prone to occur in the cranial portion of the wall they have been referred to as ventral inguinal hernias. However diverticular hernias should be distinguished from spontaneous ventral hernias (Zimmerman et al.) and hernias of the linea semilunaris (Spigelius).

Peculiarly the fascia transversalis frequently shares in the partial agenesis of the internal oblique muscle. Although Bassini, Halsted Ferguson, and others (4, 5 21 26 35) recognized this associated weakness they were more concerned with the potential weakness in the medial portion of the canal. The substitution of like generic tissue for the inadequate or missing stratum has long been recognized as fundamentally sound but there

Fig. 3. Mobilization and conversion of multifocal hernial sac. Direct and femoral locules, indirectalized. 1 iliopectineal ligament 2, inguinal ligament 3 femoral ring 4 internal ring 5, hernial sac; (a) indirect locule, (b) direct locule, (c) femoral locule and 6 epigastric vessels.

is lack of unanimity as to the best technique in accomplishing it.

(a) The reflection of the anterior rectus sheath (Woelfer Bloodgood Halsted (16), and Estes) and transfixation of its edge to the inguinal ligament was the favored technique for many years. Similarly the rectus flap has been sutured to Cooper's ligament. The objection to this type of maneuver is that a spindle shaped weakness is created between the rectus muscle and the medial margin of the flap as only a thin posterior rectus fascia with no appreciable strength is left. When the fascial defect is narrow the rectus sheath can be incised medially this allows the sheath to separate but the gap is protected by the underlying rectus muscle. The sliding graft of Falis and Tanner obviates the criticism of the reflected flap.

(b) The patch graft of Kirschner Singleton and Stehouwer taken from fascia lata, and full thickness skin grafts of Mair have been used with varying results.

(c) A massive pedicled graft of the iliotibial tract, as advocated by DeGaray and Wangen

contains the sentence "To my mind the anaesthetist is just as much a specialist as the surgeon and should

be rated as such. Surgeons in the United States might well consider this an authoritative statement

CORRESPONDENCE

PLASMA CLOT GRAFT OF PERITONEUM FOR PERFORATION OF THE STOMACH

To the Editor: In answer to the comments of Dr. Amos Koontz, concerning my article entitled "Plasma Clot Graft of Peritoneum for Perforation of the Stomach," which appeared in the August, 1947 issue of *Surgery, Gynecology and Obstetrics*, I wish to reiterate first that the method described in my article is purely an experimental one. Second, I believe that it is the first time anyone has succeeded in closing a gastric perforation by an adhesive method entirely without the use of sutures. This method was devised only in the hope that it could help in a special type of gastric perforation, not the routine small perforation. In explaining the success of the last 4 of a series of 9 experimental animals, the technique of applying the grafts was extremely important because it also included a method of at least temporarily controlling the digestive action of gastric juice. The work of Virginia Frantz, as well as that of many others, simply demonstrated the local effect of oxyel when implanted in the body tissues. Since oxyel is an acid it is my belief that it served as a temporary block against the digestive action of gastric juice just as gastric mucus does. The varying degrees of success met with, since the work of Neuhof in 1917 and Koontz in 1939 proved that a perforated hollow viscus under proper conditions could be closed with a suture patch successfully. Neuhof's method of autogenous fascial grafting and Koontz's method of ox fascia grafting were both suture methods. My method differs from both in that it is nonsuture method but is similar to Neuhof's method since it is an autogenous method using fascia-peritoneum for the posterior rectus sheath of the same experimental animal. No one denies the fact that the acidity of gastric juice is an important factor in its digestive action on tissue, other than gastric mucosa. This has been simply proved by Price and Lee. But one must recognize the fact that fascia is one of the most resistant to this action. It was thought that if a combination of factors could be developed to delay the unusual digestive action of gastric juice enough to permit the growth of gastric mucosa across the site of perforation the perforation might heal.

The healing that resulted was similar to that of those successful cases of suture patch grafting of Neuhof and Koontz. However, suture methods are not applicable in large perforations with widespread

induration. In a series of 9 dogs all were treated alike, before and after operation. Those with perforations that were sealed tightly by means of the oxyel plug, fascia peritoneum graft and pressure clamps were able to eat as soon as they recovered from their anesthetic.

Perhaps I may be able to indulge in a bit of self criticism in that no preoperative and postoperative gastric analyses were made. However this was given considerable thought before beginning the experiment and abandoned. It was felt that, first, one had to prove that a nonsuture adhesive method could be used successfully in conditions approaching the normal, before an attempt is made to apply the method to the abnormal.

In the next series of experiments, we shall attempt to make closure on animals with Mann-Williamson ulcers that have been made to perforate with histamine in beerwax.

It is thought that oxyel, whose chemical name is polyanhydroglucuronic acid, blocks gastric acidity and therefore it has been used as a plug in the experiment.

Neuhof and Koontz in some of their experimental animals performed some form of short circuit operation at the time of grafting to control the hyperacidity. Koontz even inserted bismuth subnitrate into the stomach of some of his animals. Both methods appeared to aid in successful grafting by suture methods. Others have attempted the use of continuous gastric suction to successful conclusions.

By accentuating the mechanical technique involved in my method the acidity of gastric juice was kept in mind the use of oxyel as described being thought to block this activity.

Unlike Koontz's patch of ox fascia, Frantz and others have demonstrated that no local tissue reaction results from the use of oxyel. It has been shown that at the site of implantation of oxyel, multilocular nodules form surrounded by a coagulated tissue membrane. As the oxyel becomes lysed and absorbed the coagulation is surrounded by a zone of fibroblasts and invading large monocytes. Absorption is usually followed by connective tissue scar formation. It is quite noticeable at the time of implantation of the oxyel plug that, as it becomes moist, it swells thus filling the entire cavity at the site of perforation quite snugly.

Dr. Koontz, in his comment stated, "If the implant does remain intact however the ultimate result is excellent. With this remark he helps to answer his own question. I believe that my successful experiments were due to the fact that my implants were placed in such a manner that they were able to remain intact and thus successfully produce healing of the perforation."

INTERNATIONAL ABSTRACTS OF SURGERY

steen, is a more formidable procedure but it is ideally suited to those cases with marked combined deficiency of the wall, and may be used when recurrences have followed other methods of repair.

Apart from the intrinsic causative factors of herniation, there are collateral or extrinsic factors which, if considered casually may seem remotely related. I refer to systemic maladies such as asthma and chronic bronchitis, and to biologically inferior individuals. The surgeon, therefore, should possess not only the necessary anatomical and technical knowledge to treat hernia but also the ability to recognize the structural pattern, clinical habits, and occupational requirements of the patient. Only by correlation of all factors, anatomical and constitutional, will we be able to come nearer to attaining our goal in herniology.

CONCLUSIONS

1. Reasons for the lack of general acceptance of Cooper's ligament hernioplasty have been enumerated.

2. The anatomical features and relationships of Cooper's ligament have been discussed and illustrated, and its strategic advantages in hernial repair have been pointed out. Similarly its points of vulnerability and its technical hazards have been presented.

3. The criteria for guidance in the employment of Cooper's ligament have been proposed.

4. Efforts have been directed toward dispelling certain technical as well as morphologic misconceptions in regard to the sacular classification of hernias.

5. The dictum of digital exploration and con- secutive removal of all variants of the sac, ingu- nalizing the femoral locale, and indirrectalizing the other coexisting locules, is reaffirmed as being fundamentally important in the surgical treat- ment of hernia.

6. The correlation of the sacular and mural factors is essential in selecting the technique that offers the greatest assurance of a cure of the type of hernia at hand.

7. Certain extrinsic factors, including systemic maladies, the constitutional habits, and the occu- pational requirement of the individual, should be evaluated before the selection of the most suitable repair, and these factors should play a role in the final prognosis.

COLLECTIVE REVIEW

THE PRESENT STATUS OF ARTIFICIAL INSEMINATION

STUART ABEL, M.S. M.D., Chicago, Illinois

ARTICLES dealing with considerations of the so-called test tube baby have aroused great interest in the minds of the lay public recently. It would seem that there is something of the dramatic if not of the lurid, in the discussion of some of the recent literature, and as a result of a small number of artificial inseminations carried out an attempt to re-evaluate the position of artificial insemination in the treatment of sterility seems appropriate.

It is imperative to differentiate between homologous and heterologous artificial insemination as designated by Israel. The former term refers to insemination of a wife with her husband's semen while the latter connotes the use of donor semen. The indications, techniques and medicolegal aspects of the two procedures are entirely different and it is obvious that heterologous artificial insemination carries with it certain moral and psychological implications which are wholly absent when the husband's semen is used.

From the literature and from personal communications it is evident that there are extremely diversified feelings among physicians relative to participation in the practice of heterologous artificial insemination because of the moral and legal implications. In view of the increased interest in artificial insemination during the last few years one is impressed with the need for accurate legal and theological expression. It is imperative that any consideration of the practical aspects of the procedure must include these implications.

Before proceeding to further discussion of these matters it seems propitious to present the indications and techniques of artificial insemination from a purely medical viewpoint.

INDICATIONS

Heterologous The indications for the employment of heterologous artificial insemination in the treatment of infertility seem relatively clear. Simply they consist of the established sterility of the husband and the apparent fertility of the wife. The procedure should be reserved for couples in which the husband approaches absolute sterility. The line between absolute sterility and relative infertility is difficult to draw and of course in the evaluation of any given case it must be established arbitrarily. There are cases on record in which fecundation had occurred when the sperm count had been 19,000,000 per cubic centimeter or less (311). Cary reports marital pregnancies in two couples 1 and 3 years, respectively after delivery of a child conceived as the result of heterologous artificial insemination. If a husband is thought to be potentially fertile consideration of donor semen should be abandoned and with urologic consultation fertility should be promoted if possible, to the degree where intramarital impregnation is feasible. Such efforts are certainly warranted and in these cases the use of donor semen seems unwise. Conservatism in borderline cases surely should be the rule. It goes without saying that satisfactory general and pelvic health of the wife should be included among the indications for heterologous artificial insemination.

Other indications for the use of heterologous artificial insemination have appeared in the lit

INTERNATIONAL ABSTRACTS OF SURGERY

Haibrecht has employed the procedure in cases of habitual abortion. Gierle's disease and night blindness. Potter and Wilson have reported a case in which heterologous artificial insemination from an Rh negative donor resulted in the birth of a normal child to a mother who had previously had erythroblastotic twins. A large number of constitutional or mental diseases, if present in the husband, might also be considered indications for heterologous artificial insemination. It is obvious that such indications are based upon the inadvisability rather than the inability of the husband to foster a child. Such elements are necessarily weighted more with the decisions of personal opinion and evaluation and should be made with considerable caution. I doubt that we as doctors, have the right to deliberately deny a husband the right of fatherhood, and to decide that heterologous artificial insemination of his wife is indicated, even though from the standpoint of pure eugenics such a course might at times be advantageous.

Homologous. While there is little disagreement relative to the medical indications for heterologous artificial insemination, there is by no means a comparable unanimity of opinion concerning the indications for artificial insemination by use of the husband's semen.

Cary states that the indications for the injection of the husband's specimen into the uterine cavity for the relief of sterility are relatively rare. He states that the inability of sperm cells to migrate to the cavity of the uterus because of weakness of the specimen or chemical or mechanical obstruction of the cervical canal constitutes the general indication for the procedure. Cary feels wholly unprepared to fix the standard criteria of semen defects which may justify or contraindicate the procedure.

Guttmacher makes the pertinent comment that if the spermatozoa are so pathologic that they need a 3 inch boost on their 6 inch journey they probably will be sterile anyway when face to face with a fertile egg. Guttmacher divides the indications for artificial insemination into three groups. One group considers the sterile husband and in this group a donor's semen is indicated. A second group includes the cases in which the travaginal coitus is mechanically impossible. The third group includes an "all inclusive" group of conditions which represents a composite from the works of Schorohaw, Schultz, and Cary. Listed among this all inclusive group are ante flexion, retroflexion, conical cervix, hypoplasia of the uterus, relaxed perineal body, salpingo-oophoritis, endometritis, enlarged uterus, cer-

vical stenosis, or endocervicitis and subnormal semen. There is considerable difference of opinion as to the therapeutic value of the procedure in these conditions. Guttmacher expresses an overwhelming skepticism of the value of artificial insemination in the treatment of ordinary sterility and indeed it is difficult to understand how any advantage might accrue from the procedure in the presence of many of the conditions listed. There can be little doubt of the value of homologous artificial insemination in cases in which intravaginal coitus is impossible because of hypoplasia, impotence, vaginismus, tumors, or obesity.

There are several accounts in the literature in which sterility of unknown cause" has constituted an indication for homologous artificial insemination. The latest of these appears in the September 1946 issue of *Woman's Fertility* by I. Haibrecht. His results along with those of others have not been gratifying. To employ homologous artificial insemination in such cases is to grasp at a last straw in a vein of wishful thinking as such treatment is not predicated on any scientific rationale.

Greenhill gives two reasons only for homologous artificial insemination. They are (1) the inability of the husband to deposit semen within the vagina and (2) the inability of the spermatozoa to gain access from the vagina or external os to the uterine cavity. Along these same lines Meeker has defined the indications as two and two only a persistent fault of delivery-reception and an incorrigible hostility of the endocervical secretions.

The logic of Greenhill's and Meeker's indications seems clear. Summarily, perhaps the indication for homologous artificial insemination may best be defined as those conditions which prevent the sperm from (1) gaining access to the external os of the cervix, and (2) passing through the cervix to the uterine cavity.

Included among the indications in the first group are hypospadia, vaginismus, severe dyspareunia, impotence, premature ejaculation, tumors, obesity and severe malpositions of the uterus such as severe retroversion. The second group consists of conditions in which the cervical secretions remain hostile in spite of persistent attempts to correct them.

A good deal has been written relative to hostilities of the cervix. Weinman, in studying spermigration in female secretions, lists four types of cervical hostility: mechanical, bacteriologic, chemical, and serologic. On close study of the four types there appears to be considerable

ABEL THE PRESENT STATUS OF ARTIFICIAL INSEMINATION

overlapping infection with its impaired drainage is the keynote and the production of an infected viscid mechanically obstructing mucous plug with a lowering of the pH tends to make the endocervix hostile to the upward migration of spermatozoa. The question of serologic hostility is a separate and interesting consideration. From some personal observations recently made it would seem unlikely that hostility of the cervical secretions is due to serologic incompatibility.

Whatever the composite basis for its hostility of the secretions exists as a real factor in the prevention of spermigration Huebner's test was devised to detect such incompatibilities between the spermatozoa and cervical secretions and such should be helpful in anticipating which cases might be appropriate for the employment of homologous artificial insemination. Such insemination is indicated in the presence of an unsatisfactory Huebner test only after every effort has been made to rectify cervical pathology and to improve the cervical secretions. As always, the primary effort should be directed toward treating any apparent cause for infertility rather than toward resorting to artificial insemination to effect conception in the face of pathology.

TECHNIQUE

Heterologous Perhaps a discussion of the details of the mechanical transfer of seminal fluid should be prefaced by a word of caution relative to the careful selection of patients. It has been emphasized by Guttmacher that heterologous artificial insemination should never become an assembly line procedure but that it should be reserved for couples who qualify for this somewhat radical procedure only after close evaluation. Such evaluation is obviously difficult in many instances in which a patient and her husband pay only one or two preliminary visits to the office prior to the insemination. It is imperative that the physician attempt to learn everything possible about the couple and their feeling toward the procedure. Heterologous artificial insemination should never be urged upon anyone and should only be considered when both the husband and wife solicit the services of the physician with real sincerity. If there is any evidence of reluctance or indifference on the part of either partner the procedure should be abandoned. The decision of a couple to subject the wife to artificial insemination with donor's semen should be predicated upon a thorough knowledge of the procedure in all its implications. It is within the physician's province to acquaint prospective couples with these aspects in much the manner in which they

appear in this article. A continued desire to proceed, after full realization of all the ramifications of the procedure, should testify to the couple's sincerity of intent, and should qualify them among the carefully selected group.

Even though patients are carefully selected, I believe, unlike Guttmacher that signed papers are necessary for the protection of the physician. Both the husband and wife should sign such a paper which expresses their desire for the physician's services relative to the procedure and which absolves him from any responsibility concerning complications which may arise from it. Legal documents should be drawn up with the aid of counsel and should be considered only as protection for the physician. Such papers should be kept in a private vault and not with other accessible office records.

The selection of the donor should likewise be undertaken with care and only by the physician. Prearrangement whereby a blood relative serves as the donor is fraught with potential emotional hazard and possible social and legal repercussions. Complete anonymity is imperative. Consequently the selection of the donor is entirely the physician's responsibility. Barton and others have given a detailed account of the various factors which they deem important in the selection of donors. Included by them among the requirements for selecting the donor are (1) he should have at least two children of his own, (2) he must be of mature age so that his character and reliability can be assured and (3) his sperm count must be over 30 million.

In our own small series of cases, we have used as donors the members of the house staff of two university affiliated hospitals or students from the medical school doing senior hospital work. Such individuals have been unmarried in most instances and this lack of family has not appeared as a disadvantage especially in view of the anonymity of the procedure. Under such conditions the lack of an available object for the parental drive seems of lesser importance. Such donors are for the most part of a younger age group than that felt to be advantageous as these workers have confessedly stated that one of their chief difficulties lies in the fact that most mature men have low fecundity. I wonder if the younger intern group might not offer more advantage insofar as higher fertility is concerned. Surely an intern has begun to manifest enough evidence of character so that his value as a potential donor can be determined. The arbitrary standard of 30 million sperm per cubic centimeter seems low in

INTERNATIONAL ABSTRACTS OF SURGERY

considering that we have free reign in the donor selection. Perhaps twice or three times this sperm count would be more appropriate as a minimum. Every effort should be made to select donors who enjoy excellent health and in whom the family history is satisfactory. Physical and racial similarity to the husband should be observed. The use of specimens from more than one donor or the use of a donor "pool" would increase the anonymity of the procedure and perhaps warrants a trial. If the wife is found to be Rh negative an Rh negative donor should be used. One donor is capable of siring a great many children and if anonymity is maintained it is feasible that many may become numerous in any given community without knowledge of the fact. Intermarriage is at least a theoretical possibility and such a danger should restrict the use of a single donor to a small number of cases.

COLLECTION AND TRANSFER OF SEMINAL FLUID

The collection and transfer of seminal fluid should be carried out in such a way as to approximate as closely as possible the physiology of normal intercourse. Such procedure is simple of execution. The specimen is collected in a clean glass preferably by masturbation. Although there may be some psychological or moral disadvantage inherent in this method, the cleanliness of collecting the specimen, the definite control of time factor and the convenience to all parties concerned make it most practical. Much has been written relative to the duration of viability of normal sperm. There is no question that specimens will remain potentially fertile for several hours and perhaps much longer if they are kept cool. However there is no need for delay in making the transfer. Nature does it directly and present a contradiction to the physician's attempt to simulate nature. It is not impractical to have the patient prepared prior to the collection of the specimen.

There have been variations described in the technique of injecting the seminal fluid. It is essential to realize that we are dealing with normal spermatozoa and with a woman of predetermined normal fertility. Insofar as such a factor can be evaluated. Consequently all that is essential is to deposit the semen upon the external os in as simple a manner as possible. This is best done by placing the patient in lithotomy position and exposing the cervix with a speculum. The entire ejaculate is drawn into a clean 5 to cubic centimeter syringe with Luer adaptor and is expressed onto the external os of the cervix. There

is no indication for intrauterine or intracervical insemination. Such a procedure is unphysiological and carries no inherent advantage. The patient is kept in the dorsal position with hips elevated for from 20 to 30 minutes and then allowed to leave. Cary has performed the insemination with the patient in Sim's position and then kept her in the dorsal position for the ensuing half hour. Halbrecht says that his patients sit quietly for 10 or 15 minutes and are not required to lie down. Preliminary douches of fortified Ringer's solution as described by Hotchkiss and MacLeod, or by Halbrecht are of unproved value in heterosexual artificial insemination. The latter author states that such douches did not affect his results.

It is apparent that if the procedure is to meet with success it must be carried out during the fertile portion of the menstrual cycle. All adjuncts to the determination of the time of ovulation are of value. Studies of the time of ovulation, fertile period, and recordings of basal temperature are all helpful. In general it may be said that the most likely time for artificial insemination is on the fourteenth day prior to the onset of the subsequent menstrual period. If 3 trials are carried out each month at a day intervals with the second trial falling on the optimal date, the chance for success is excellent.

There is, of course, no way to anticipate how many efforts may be required to effect conception in any given case. Success is in part a matter of chance just as it is in normal fertile marriages. It is well to explain to prospective patients and donors that repeated efforts may be necessary. They may become discouraged if pregnancy is not promptly achieved. There have been cases reported in which success followed only after months and even years of effort. If after 3 months the donor is changed. Incidentally the donor fee has been arbitrarily established at twenty-five dollars the first month and ten dollars the second and third months, a total of forty five dollars for 9 specimens, if 9 are needed.

In brief, the technique of heterosexual artificial insemination should be made as simple as possible and should attempt to reproduce the process of normal intercourse. It occurs physiologically during

Homologous The semen specimens for insemination from husband to wife are collected by coital intercourse, coitus interruptus, or coitus, and preferably from a practical standpoint, by

turbation. Prompt transfer of the specimen byotomy and slight Trendelenburg position of the patient, exposure of the cervix, and selection of the optimum period of the month are all carried out as described under heterologous artificial insemination. When the indication for artificial insemination from husband to wife is because of faulty delivery of the sperm to the external os, for one or more reasons as given under indications, the transfer is made directly to the external os as described for the use of donor semen. Once more efforts should be directed toward reproducing the physiology of normal intercourse. Barton and others have allowed the wife to practice self insemination in cases in which impotence, dyspareunia or ejaculatory failure were the indications. Such inseminations were of course intravaginal. It seems that the procedure would be better controlled by the physician with the cervix under direct vision and the patient in lithotomy position.

However it is the group in which hostile cervical secretions represent the indication in which there is definite difference of opinion relative to the detail of technique. Guttacher and Cary advocate intrauterine insemination in this group. Cary warns that not more than 0.6 cubic centimeter of semen is used so as to avoid getting it into the tubes or abdominal cavity where colic or possibly inflammatory reaction may occur. Barton and her coworkers have placed the cannula from $1/4$ to $1/3$ inch into the cervix in cases of defective cervical invasion and have very carefully injected a small quantity of semen. They fully injected a small quantity of semen as recommended against forceful injection as recommended by Guttacher and others because of the danger of getting semen into the endometrial cavity. Israel points out the fact that the irritating effect of semen may institute uterine contractions which tend to prevent the upward migration of spermatozoa. The menstrual-like cramps occurring immediately after occasional intracervical inseminations in which some semen may have entered the uterus, lends credence to Israel's contention. Halbrecht (10) has abandoned the intrauterine method because it was not without harm and required cervical dilatation. Intrauterine artificial insemination seems to be the most logical in these cases. In intrauterine insemination, as described by the Germans, the patient is hospitalized, taken to the operating room, and is semiconscious under sterile conditions with a catheter in the uterine cavity however this method seems to offer no advantage and is fraught with potential hazard. Even under favorable circumstances semen cannot be considered sterile

Bickers reports a case in which a pelvic abscess developed following an insemination in which some fluid entered the uterine cavity and points out the danger of uterine insemination because of the fact that semen is not sterile. Franz has reported a case of fatal sepsis which followed intrauterine technique.

Guttacher has reported that he has been working on the so-called spreading factor of Schwenk and Tislowitz. It is a testicular enzyme which dissolves mucus and has been applied to the cervix prior to artificial insemination. Any benefit therefrom remains unestablished. Guttacher also comments on the fact that only 1 conception has followed insemination by material aspirated from the testis and points out the uselessness of this procedure.

RESULTS

It is exceedingly difficult to evaluate the results of artificial insemination subsequent to a review of the literature. The indications for the procedure in the hands of different authors are quite varied and are often not clearly given. There is commonly no definite differentiation between heterologous or homologous types, especially among the early writers. The technique has been as varied as the indications, sometimes being described as intrauterine, sometimes as intracervical, and sometimes as intravaginal. The number of inseminations each month as well as the number of cycles through which efforts have been maintained differ among various authors. With so many variables, statistics are difficult of interpretation.

Among the early reports is one of Schorohowa which lists 88 cases with 33 successes there is a paucity of detail reported. Seguy reported on two series. The first consisted of a total of 24 treatments to a few women with no success. The second included 16 cases, among which there were 7 unsuccessful results. A donor specimen was used in 2 cases. Schultze achieved 15 successes among 102 cases.

If the more dependable results of the recent works of Cary, Israel, Guttacher, Halbrecht, and Barton are grouped together we find 87 successes among 174 attempts at heterologous artificial insemination and 17 successes among 119 attempts at homologous artificial insemination. The ratios are seen to be exactly 1 to 2 and 1 to 7 respectively. It is interesting to note that among the attempts at homologous artificial insemination reported by Halbrecht and Guttacher there was a total of 65 cases in which the indication was infertility of unknown

INTERNATIONAL ABSTRACTS OF SURGERY

cause. There was only 1 success in this entire group. The remaining 16 successes reported by all 5 authors were achieved in cases in which the indication was abnormal spermiation, impotence, hypospadias, or cervical obstruction.

The small group of cases accumulated by the author correlates well with the over-all summary of the work described. There have been 7 patients in whom heterologous artificial insemination was employed. In 1 the procedure succeeded twice and in 3 others, once. There have been 3 failures in 8 attempts. The patient in whom there were 3 successes became pregnant in both instances after only 1 month's effort consisting of 3 inseminations. One patient was successfully impregnated after 2 months of such effort 1 after 6 months, and 1 after 14 months. One of the 3 patients in whom failure occurred disappeared after 7 months and the 2 others, both of whom live out of the city temporarily discontinued the inseminations after 6 months. They both plan to resume efforts. The indication for use of donor semen was either severe oligospermia or azoospermia in every instance. In the 5 successes, 2 normal deliveries ensued and 3 patients are currently carrying the pregnancy.

There have been 8 cases in which the author has used the husband's semen. Seven of these have been couples who had no demonstrable cause for infertility. In none of these cases has pregnancy ensued. It is the lack of success in this group both in this small series and in others reported which has led to the feeling that homologous artificial insemination is helpful in only very special and limited conditions as outlined under the indications. In the eighth case in which homologous artificial insemination was used the result was successful and a normal infant was subsequently delivered. The indication was severe retroversion of the uterus, and marked, persistent cervicitis with an unsatisfactory Huebner test.

Seymour and Koerner in 1941 published an article purporting to describe the results of artificial insemination in the United States as reported by 7 642 physicians in answer to a circular which was sent to 30,000 physicians who might be in a position to do artificial inseminations because of the nature of their practices. These reports included some very remarkable statements. It was concluded that nearly 10,000 pregnancies had been achieved through artificial insemination, two-thirds of these with the husband's semen. The proportion of boys to girls was 8 to 5 when the husband's semen was used and 7 to 5 when a donor's semen was employed.

Ninety-seven per cent of all successful inseminations resulted in live babies. The incidence of stillbirths was practically negligible and the incidences of ectopic pregnancy and miscarriage were one-sixth and one-fifth, respectively, of the figures usually given as normal. All living children were born normal in every respect. It is estimated that nearly 400 surgical operations were prevented because of the use of artificial insemination.

It is little wonder that Folson expressed criticism of this survey in the light of such startling conclusions. His feeling that "perhaps man can populate more efficiently and with greater fetal salvage quantitatively and biologically without the distracting preoccupation of sexual congress is easy to understand if one is to accept the figures given. The results of such a survey necessarily poorly controlled and without documentary evidence should be received with great caution. Is it not wiser to study closely the individual reports in the literature which represent the efforts of workers in the field who have made a detailed investigation of artificial insemination in all its aspects?

LEGAL ASPECTS

Heterologous The medicolegal aspects of heterologous artificial insemination are woefully ill defined. There have been few articles in the literature relative to the legalities involved. It is obvious that the paucity of expression stems from the fact that the procedure with all its implications has never been presented to a court of competent jurisdiction in this country for determination. Consequently there has been no judicial expression on the issues involving the procedure. Such issues might be properly divided into problems particularly concerning (1) the child, (2) the wife and her husband, (3) the donor, (4) the physician, and (5) the procedure as a whole.

As to the child, on May 6 1939 an editorial appeared in the Journal of the American Medical Association entitled, "Artificial Insemination and Illegitimacy" (4). This editorial revealed that the presumption of law that a child is legitimate when born during wedlock is not conclusive and can be overcome today when proof is offered that the mother's husband cannot be its father. If in artificial insemination a donor's semen is used that the husband seems to be illegitimate. The fact that the husband has given his consent to the procedure has no bearing on the child's legitimacy. Unless the husband adopts such a child it remains a bastard issue and as such cannot acquire in-

ABEL THE PRESENT STATUS OF ARTIFICIAL INSEMINATION

heritable rights from the husband. Usually only the wife, the husband and the physician know of the procedure but relatives may discover the details, and problems of legitimacy and inheritance may arise. The editorial states that it is the just due of the child that false pride or considerations of delicacy be put aside and that it be given through adoption, the protection the husband intended when he consented to the procedure.

It has been stated by one legal authority that society has evolved certain concepts as to immorality and illegality with respect to bastard issue because of conditions under which it comes into being and the dangers it fosters on the community and on the offended husband. Such an analogy does not exist with respect to the issue resulting from heterologous artificial insemination. Whether the court would entertain a similar interpretation remains among the undecided problems.

The chief problem concerning the wife and her husband is that of adultery. Although as stated above there has been no determination of this problem by the courts in this country it is interesting to note in this connection the decision of the Supreme Court of Ontario in a case involving heterologous artificial insemination performed in England on a married woman whose husband was in Toronto. This decision rendered in 1921 intimated very strongly that a married woman who submits to an artificial insemination the donor being a man other than her husband commits adultery. In this case the husband had no knowledge of the procedure.

However it seems that adultery as defined in common law or statute contemplates sexual intercourse. This of course is not true of a woman submitting to heterologous artificial insemination. Whether or not such a procedure might be interpreted as adultery in present day courts in this country remains undetermined.

The donor probably has no legal liability with respect to the procedure although if he misrepresents his heredity or his physical condition it is conceivable that a liability might accrue. It is also possible that further legal issues might arise because of the fact that the donor is married.

As to the physician there is first of all the question of legal protection in the form of written consent to the procedure. This should obviate any future action by the husband or wife against the physician. The nature and limits of the physician's responsibility in selecting the donor are among the problems not yet determined by law or defined by the courts.

As to the procedure as a whole the Bureau of Legal Medicine and Legislation for the American Medical Association has made the following comment in an unpublished communication in response to a query.

It has been argued that public morals are necessarily injured by attempted assignments of sex rights and prerogatives and by the wilful production of bastard issue that every child of strange or questionable paternity is a reproach to morality that any procedure which produces an illegitimate is in itself necessarily illegal that the procedure nullifies the legislative intent concerning sexual monopoly between husbands and wives and that the procedure itself tends to the degradation of the resulting child. For these reasons it has been argued that all participants in the procedure the physician the patient, the husband and the donor might be guilty of violating a statute common in most states making it a criminal offense for two or more persons to conspire to do any illegal act injurious to public morals.

The bureau then attempts to refute the above arguments. It is pointed out that heterologous artificial insemination is not an assignment of sex rights. There is no consent to intercourse by a third party nor to any other rights the husband has in his wife. The procedure is scientifically and privately done. Because society has not yet had time to evolve any opinion as to the morality of the procedure, such procedure can hardly be called immoral. And inasmuch as there is no law which would apply to the matter either written or unwritten, there can be no decision as to the legality of it.

There is still another point of confusion incident to the legal interpretation of signed contracts purporting to the adoption of the unborn child. Even though the husband has consented in writing to adoption following heterologous artificial insemination of his wife it is problematical that a court of chancery would uphold such a contract for specific performance in the event that the husband changes his mind for one reason or another after the child is born.

These problems have been enumerated as evidence of the multiplicity of legal issues, all of which are incident to heterologous artificial insemination and which are unanswered in the light of competent court decisions. The views expressed represent the opinions of the Bureau of Legal Medicine and Legislation of the American Medical Association. They are confessedly offered as personal opinions in the absence of judicial precedent.

cause. There was only 1 success in this entire group. The remaining 16 successes reported by all 5 authors were achieved in cases in which the indication was abnormal spermatogenesis, impotence, hypospadias, or cervical obstruction.

The small group of cases accumulated by the author correlates well with the over all summary of the work described. There is still another point of confusion incident to the legal interpretation of signed contracts purporting to the adoption of the unborn child. Even though the husband has consented in writing to adoption following heterologous artificial insemination of his wife it is problematical that a court of chancery would uphold such a contract for specific performance in the event that the husband changes his mind for one reason or another after the child is born.

These problems have been enumerated as evidence of the multiplicity of legal issues all of which are incident to heterologous artificial insemination and which are unanswered in the light of competent court decisions. Some of the views expressed represent the opinions of the Bureau of Legal Medicine and Legislation of the American Medical Association. They are confidentially offered as personal opinions in the absence of judicial precedent.

It has been stated or inferred often in the literature that it is extremely difficult to evaluate the morality or legality of heterologous artificial insemination because of the novelty of the procedure. When one considers and realizes that the number of cases in which the procedure has been done must now be expressed in thousands, it is difficult to reconcile novelty with the inadequacies of the legal machinery governing heterologous artificial insemination. It is perfectly obvious that all the legal opinions relative to the procedure are struggling to interpret it within the boundaries of ancient statutes and common law dealing with illegitimacy and adultery. At the time such laws were formulated artificial insemination had not made its necessarily but unfortunately surreptitious entrance into medical practice and literature. Consequently they were never meant to encompass all the implications of the procedure.

In a paper given before the Interstate Postgraduate Medical Assembly of North America in 1943 (8) Guttmacher makes the rather startling recommendation that hospital records and birth certificates be falsified in the event that the physician delivers the child begotten as the result of heterologous artificial insemination he has done. No one will question either the sincerity of purpose or the illegality of such a recommendation.

Again in their article on artificial insemination, which appeared in the *British Medical Journal* in January 1945 Barton, Walker and Weisner (1) state that couples are informed that the child will be legitimate if the husband is registered as the father. In their hands such registration is demanded although they realize it constitutes an offense.

Here then are examples of reputable physicians recommending or demanding the execution of illegal acts in good faith because they feel that by so doing they can render their patients a real medical service. Even the most conservative must acknowledge that in selected instances a genuine medical service is rendered to barren couples by the use of heterologous artificial insemination. If the patient is referred for delivery to an obstetrician who is unaware of the artificial insemination no deliberate execution of illegal acts is committed. This is a partial solution to the problem. There is a need for legal recognition of this procedure which is appearing more and more frequently in the medical literature. Recommendations and demands such as presented by Guttmacher and Barton and others can scarcely be condoned. What then is the answer?

It would seem logical that the first step lies in the creation of adequate legislation, which in

taking full cognizance of all the implications of heterologous artificial insemination would establish the legal machinery necessary to regulate the procedure in all its aspects. The impetus for such legislation might come from the legal bureau of the medical societies, perhaps most appropriately from the Bureau of Legal Medicine and Legislation of the American Medical Association, pending consideration of the problem by the assembly of delegates, or from the various state medical societies. The legal status of the procedure would thus be determined by law although still untested by the courts. Some clarification of the legal aspect of the problem is imperative to enable the physician to understand how he may best serve his patient and still remain within the law. Perhaps it would not be inappropriate to consider the following legislation which would primarily protect the child.

Any child conceived and born as the result of the impregnation of his mother by artificial insemination by a duly licensed physician or under his advice and direction, and upon the written consent of herself and her husband, shall have all the rights, privileges, and obligations of a child conceived and born as the result of impregnation through sexual intercourse of the husband and the wife and no evidence concerning such artificial insemination shall be received in any action at law in equity or other legal proceeding which in any way may impair his rights, privileges, or obligations."

Artificial insemination is a modern procedure and it is time that society take a modern stand on the problem even though it finally may define it as illegal, to be considered in the same category as criminal abortion. At least any stand would constitute a bit of *terra firma* in a sea of uncertainty. However it is unlikely that the procedure will be considered illegal in later years.

Homologous. The legal issues incident to insemination with the husband's semen are practically negligible. It is conceivable that some liability might accrue relative to the source of the semen used. If the specimen is given to the physician by the husband in the wife's presence and the procedure is immediately carried out, all doubts should be dispelled.

THEOLOGICAL ASPECTS

When a physician is consulted by couples desirous of a pregnancy via the route of artificial insemination, he is faced with not only medical problems but theological problems as well. I believe it behooves us to consider and respect the views of different religious groups as they

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Reld J L., and McGuckin F: **Cavernous Sinus Thrombophlebitis—A Report on 6 Consecutive Recoveries.** *J Lar Otol* Lond. 1946, 61: 273

The authors present the cases of 6 patients who recovered from cavernous sinus thrombophlebitis, merely to illustrate the improvement in prognosis with the use of penicillin and sulfonamides.

In conclusion they state that without suggesting that cavernous sinus thrombophlebitis has ceased to be a grave lesion it is clear that the prognosis has been radically altered. Intensive modern therapy, preferably combining sulfonamides and penicillin, is justified even when the case by previous standards appears hopeless.

G ALAN LIVA, M D

EYE

Klakadden W S. and McGregor M W: **Coloboma of the Eyelids.** *Plast Reconstr Surg* 1947 2: 60.

The authors report a case of the relatively rare condition of bilateral congenital coloboma of the upper eyelids. The surgical treatment of this condition is not always easy and if the results are inadequate or surgical correction is delayed, corneal scarring and impaired vision may result. This patient was one week old when first seen. In spite of frequent boracic irrigations and adequate application of boracic ointment, corneal ulceration gradually developed in both eyes during a period of 2½ months. At this time plastic reconstruction of the lids was done. The results were entirely satisfactory. The method of reconstruction was then compared with other methods of surgical correction of coloboma of the eyelids.

ROGER H. JOHNSON M.D

Fox, S. A.: **Lid Repair and Reconstruction.** *Am J Ophth.* 1947 30: 190.

The author describes the reconstruction of an obliterated eye socket with epidermis. He points out that Wheeler first presented this method in 1921. After the eyelids are dissected from the orbital canthi a tents to the periosteum and behind the canthi a dental compound is fitted into the socket. Around this stent, an epidermic graft is wrapped with its epithelial surface directed inward.

Instead of dental stents Fox recommends the use of acrylic forms which range in size from 42 by 32 mm. to 38 by 22 mm. and are from 3.5 to 4 mm. in thickness. The most frequently employed form is the 38 by 28 mm. size. After all the fibrous and granulation tissue has been excised epidermis approximately 3 by 4 in. in size and from 0.010 to 0.012 inch

in thickness is cut from the inner middle aspect of the arm. The dermatome cement enables the graft to adhere to the form. The eyelids are not sutured together but a patch is applied, over which a firm pressure dressing is placed. The eye dressing is removed after 7 days and a pressure bandage is reapplied for five more days. The form is removed, the socket irrigated and all excess epidermal tissue cleaned away. At the end of another week, a permanent prosthesis may be inserted.

Although the technique does not differ much from Wheeler's method reconstruction is expedited and facilitated by the use of the acrylic forms. The graft obtained with the use of the acrylic forms is uniformly thin and is a great improvement on grafts obtained with a knife. The latter contain sebaceous material and debris which tears mucus, and debris may collect and stagnate and in which low grade infections may occur.

JOSEPH ZUCKERMAN M.D

Kreusner W E. III: **Surgical Methods of Treating Paralysis of the Superior Oblique Muscle.** *Arch. Ophth.* Chic. 1947 37: 121

The author describes various methods used in the surgical treatment of paralysis of the superior oblique muscle. He stresses the disadvantages of weakening a depressor muscle and believes that weakening an elevator muscle is preferable since the need for binocular vision is more pronounced in the lower field. The final criteria depend on the measurements in the individual case. Adequate diagrams are given.

HUTCH H. ROMANOS, M.D

Gibson G G: **Marginal Myotomy: Analysis of 22 Cases.** *Arch. Ophth.* Chic. 1947 37: 175

The use of marginal myotomy is advocated in the treatment of cases of concomitant strabismus of low degree in children in place of bilateral recession according to the method of Chavasse. The operation is performed on each internal rectus muscle posterior to the tendon which is said to produce a greater effect. Two incisions are placed in the margins of the muscle directly opposite to each other so as to cut all but the central 2 or 3 mm. of muscle.

Twenty two patients have been operated upon by this method with what the author considers fair success, although several had recurrences. Orthoptics treatment was not employed.

WILLIAM A. MANN M D

Hughes, W F Jr: **Treatment of Lewisite Burns of the Eye with Dimercaprol (Bal)** *Arch. Ophth.* Chic. 1947 37: 25

The author discusses the factors concerned in the destructive lesions caused by lewisite burns of the

may apply in the case of any given patient. Our own views on the morality or immorality of artificial insemination are not by any means the only consideration. If we are to perform a real and honest service to patients and society it certainly is within the realm of duty to have an understanding of the stand taken on the problem by the various churches and to consider the spiritual well being of the family involved. Knowledge by both physician and patient of the theological views on the performance of artificial insemination is essential in the decision as to whether or not the procedure will contribute to the overall happiness of the family. Here then is another factor to be considered in the careful selection of cases.

It is interesting to examine the views held by the various religious groups. The problem has been most definitely defined by the Roman Catholic Church. In March 1897 the Holy Office issued a decree approved by Leo XIII condemning artificial fecundation as illicit. Apparently the decree referred to masturbation as methods of obtaining germ cells. There has been much discussion as to whether any form of artificial fecundation is permissible. In order to expedite this consideration homologous and heterologous artificial insemination will be considered separately.

The question of homologous insemination has been considered by Gerald Kelly, S. J. in a paper entitled *The Morality of Artificial Fecundation* which appeared in the *Ecclesiastical Review* (14) Six say that the procedure is illicit and 7 say that it is at least probably licit. The conflict apparent in differences of opinion relative to the interpretation of the obligations contracted by the husband and wife in marriage. Those who say that it is illicit believe that sexual intercourse is the only obligation that each partner acquires and that the right to propagate is only an illicit feel that the right of propagation is a direct right of married people in much the same way that self preservation is the right of an individual failing normal means, he may use abnormal or artificial forms of nourishment. So it seems that married people when unable to generate by the normal means of sexual intercourse, may use abnormal means provided that means be not sinful. An intrinsically unlawful means is never permissible even though it be directed toward achieving a good end. Included by Kelly among

permissible means of homologous artificial insemination are the forcing of the spermatozoa from the vagina into the uterus by means of a syringe and the utilization of a hypothetical instrument to facilitate the passage of spermatozoa into the uterus.

From a practical standpoint these methods carry obvious inherent disadvantages. It has been suggested to me by an authority in scholastic philosophy a faculty member in a leading Catholic University that use of a perforated condom is probably permissible. The perforation, necessarily made so as not to interfere with the fundamental intent of the procreative act may be very small so as to enable the physician to utilize at least a portion of the specimen in making the transfer to the cervix.

In brief it may be stated that homologous artificial insemination is considered permissible in the Roman Catholic Church only if the means of accomplishing this end are not intrinsically sinful.

The employment of heterologous artificial insemination is on the other hand not permissible in any sense. Gerald Kelly in the above mentioned paper states that this procedure is against the laws of nature and that philosophically such a compact to care for the child would be termed accidental. He further states that married parties have no power to give such consent. The right of propagation taken directly or indirectly to the right of intercourse is in either case exclusive of a third party. Consent by the husband does not take away the injury to the marriage bond as established by God.

The artificial transplantation into the genital tract of a woman of spermatozoa from a man other than her husband constitutes a portion of the procreative act indeed the most important part, and as such must be interpreted in the eyes of God as adultery.

Another objection raised by the Roman Catholic Church is based on the fact that except for the highly impractical and unsuccessful method of testicular aspiration, all methods of obtaining spermatozoa are not permissible. There is then no way in which heterologous artificial insemination is reconciled to the moral philosophy of Roman Catholicism.

The views taken by the Episcopal Church are in essence the same as those expressed more definitely and legalistically by the Roman Church. There is no detailed consideration of the problem of homologous artificial insemination but the procedure is entirely acceptable. The use of donor semen however is condemned on the

grounds that such a means of insemination constitutes adultery.

The views held by the various protestant churches and the Reformed Jewish Church apparently have not been crystallized in print. For the most part it is safe to say that such views will attempt to concur with whatever state laws may be passed. Inasmuch as there is nothing in the Scripture forbidding it each protestant and reformed Jewish couple may follow their own wishes toward artificial insemination.

The Orthodox Jewish synagogue has taken no definitely expressed stand on the matter as yet. It is probable that homologous artificial insemination will be perfectly acceptable. However inasmuch as an orthodox Jewish marriage is only consummated at sexual intercourse, there is a distinct possibility that a child born to an orthodox Jewish couple as a result of heterologous artificial insemination may be considered as a bastard issue. The child would be conceived without sexual intercourse, a situation incompatible with consummate marriage. This concept is not the official expression of the synagogue but only the composite of personal expression among several rabbis.

Summarily homologous artificial insemination may be considered as compatible with the moral philosophy of all the common churches, if the Roman Catholic views on the means of achieving the result are respected. Heterologous artificial insemination, on the other hand, constitutes adultery in the light of Roman and Episcopal theology and it is possible that the Orthodox Jewish Synagogue may consider it conducive to the production of bastard issue although there has been no official expression on the subject as yet. Heterologous insemination is acceptable to the Reformed Jewish Church and the various Protestant Churches insofar as it concurs with existing state laws at least there is no definite expression against it.

SUMMARY

In accordance with the increased interest manifested in artificial insemination, an attempt has been made to present some of the practical aspects of the procedure in all its implications. Homologous and heterologous types are defined to differentiate between the use of semen from the husband and a donor respectively. The indications and techniques for each type are discussed. The results obtained by several investigators are reviewed and the author's small series is presented. The procedure is discussed from the standpoint of its legal and theological implications.

CONCLUSIONS

1. Heterologous artificial insemination may be considered when the wife is fertile and the husband sterile. It should be employed only after all efforts to improve the husband's fertility have failed. Constitutional or familial disease constitutes a doubtful indication.

2. Homologous artificial insemination is indicated in relatively few instances. It is not indicated as a last resort in cases in which no cause for infertility is found. It is indicated in conditions in which the spermatozoa are not transported to the cervix, as in impotence, dyspareunia, hypospadias, vaginismus, premature ejaculation, tumors, obesity and severe malpositions of the uterus. It is also indicated in those few cases in which the cervical secretions remain hostile in spite of persistent treatment and in which the Huchner test proves unsatisfactory.

3. The technique of insemination should be carried out cleanly and promptly and every attempt to reproduce the process of insemination as it occurs physiologically during normal intercourse should be made. In homologous insemination when hostile secretions represent the indication, the semen should be deposited within the cervix. In all other types of insemination the semen should be deposited upon the external os of the cervix. Insemination into the endometrial cavity is unsafe and not indicated.

4. If the given indications for homologous artificial insemination are observed the results are favorable. They are also good in the use of donor semen. However sustained effort may be necessary to achieve success just as a pregnancy is often accomplished in normal couples only after months of effort.

5. The legalities of heterologous insemination are a problem. The lack of legislation and judicial precedent relative to the procedure make for confusion and uncertainty. The time has come for legal recognition of the problem.

6. There are no real or practical theological objections to the use of husband semen, but the Roman Catholic, Episcopal, and perhaps the Orthodox Jewish Churches frown upon the use of donor semen.

7. Heterologous artificial insemination is a "radical" procedure. It should be considered after all efforts at treating infertility have failed. Prospective couples should be chosen with utmost care. The problem should be explained to them in full, including the legal and theological aspects. If when fortified with this knowledge, both husband and wife are enthusiastic to proceed, it

may be resorted to by the physician in the light of a real service rendered.

Heterologous insemination is acceptable to the Reformed Jewish Church and the various Protestant Churches insofar as it concurs with existing state laws at least there is no definite expression against it.

SUMMARY

In accordance with the increased interest manifested in artificial insemination, an attempt has been made to present some of the practical aspects of the procedure in all its implications. Homologous and heterologous types are defined to differentiate between the use of semen from the husband and a donor respectively. The indications and techniques for each type are discussed. The results obtained by several investigators are reviewed and the author's small series is presented. The procedure is discussed from the standpoint of its legal and theological implications.

CONCLUSIONS

1. Heterologous artificial insemination may be considered when the wife is fertile and the husband sterile. It should be employed only after all efforts to improve the husband's fertility have failed. Constitutional or familial disease constitutes a doubtful indication.

2. Homologous artificial insemination is indicated in relatively few instances. It is not indicated as a last resort in cases in which no cause for infertility is found. It is indicated in conditions in which the spermatozoa are not transported to the cervix, as in impotence, dyspareunia, hypospadias, vaginismus, premature ejaculation, tumors, obesity and severe malpositions of the uterus. It is also indicated in those few cases in which the cervical secretions remain hostile in spite of persistent treatment and in which the Huchner test proves unsatisfactory.

3. The technique of insemination should be carried out cleanly and promptly and every attempt to reproduce the process of insemination as it occurs physiologically during normal intercourse should be made. In homologous insemination when hostile secretions represent the indication, the semen should be deposited within the cervix. In all other types of insemination the semen should be deposited upon the external os of the cervix. Insemination into the endometrial cavity is unsafe and not indicated.

4. If the given indications for homologous artificial insemination are observed the results are favorable. They are also good in the use of donor semen. However sustained effort may be necessary to achieve success just as a pregnancy is often accomplished in normal couples only after months of effort.

5. The legalities of heterologous insemination are a problem. The lack of legislation and judicial precedent relative to the procedure make for confusion and uncertainty. The time has come for legal recognition of the problem.

6. There are no real or practical theological objections to the use of husband semen, but the Roman Catholic, Episcopal, and perhaps the Orthodox Jewish Churches frown upon the use of donor semen.

7. Heterologous artificial insemination is a "radical" procedure. It should be considered after all efforts at treating infertility have failed. Prospective couples should be chosen with utmost care. The problem should be explained to them in full, including the legal and theological aspects. If when fortified with this knowledge, both husband and wife are enthusiastic to proceed, it

construction of the disturbed anatomy of the eye has to be considered. The healing process and the fate of the perforated eye depends chiefly on the initial surgical treatment. The simplest and most successful method is to suture the sclera rather than only the conjunctiva.

The epithelium, the episclera, the suprachoroides, and the conjunctiva participate in the process of regeneration of wounds. The presence of regenerative tissue in the anterior chamber with resultant increase in the intraocular pressure in a wounded eye is of practical interest.

Proliferation of bands of tissue inside the eye which lead to atrophy of the eyeball are the products of "super regeneration" of the wound.

Proper closing of the wound is the first requisite for a good result. The edges of a wound should be correctly coated through the entire depth of the wound. Regulation and depression of the regenerative process by chemical and other methods is a second requisite.

The author points out that the extraordinary intensity of the regenerative process in the sclera and cornea may result in unfavorable conditions such as surplus growth with penetration by the regenerative tissue into the fluid media. The experience of histologists should be enlisted and their knowledge of regulation of the growth of the tissue elements should be applied.

It is also pointed out that although clinically similar autonomous fibromatosis in the eye has nothing in common with sympathetic ophthalmia.

JOSEPH ZUCKERMAN, M.D.

Newell, Frank W.: Traumatic Iridodialysis with Repair. *Am. J. Ophth.* 1947 30 695

Separation of the ciliary border of the iris from its attachment may occur spontaneously in atrophy of the iris root or may follow blunt ocular contusions. Small defects need not be treated but those large enough to cause symptoms should be corrected surgically provided there are not too many complications.

The author presents a case in which the eye had been struck by a small branch causing no damage except a separation of the entire nasal attachment of the iris from the ten to seven o'clock meridian. The pupil moved temporally. Because of the diminution of vision, dazzling and photophobia, surgery was done. A small conjunctival flap was prepared, a corneoscleral suture placed at two o'clock, and a small keratome incision was made between the loops of the suture. The peripheral border of the iris was grasped with an iris hook and drawn into the wound without prolapsing the iris. The suture was tied and the flap drawn over the wound. Five weeks later a similar operation was performed at the five o'clock meridian. The latter procedure formed a round pupil and left 3 small peripheral defects between the areas of attachment. There were no further symptoms and the patient had a corrected vision of 20/20 in that eye.

Reattachment of an iridodialysis will occasionally occur spontaneously but is so uncommon that it is usually corrected surgically either by an iridectomy by a reattachment to a fresh surface within the anterior chamber or in some cases by incarceration of the iris in a corneoscleral wound.

ROGER H. JOHNSON, M.D.

Ghändler, Paul A., and Johnson, Carl C.: A Neglected Cause of Secondary Glaucoma in Eyes in Which the Lens is Absent or Subluxated. *Arch. Ophth.* Chic. 1947 37 740.

The authors describe a neglected cause of secondary glaucoma in eyes in which the lens is absent or subluxated. Glaucoma which develops in aphakic eyes spontaneously or following dislocation of a membrane may result from many factors which ultimately result in extensive peripheral anterior synechias. These factors include delayed reformation of the anterior chamber, prolapse of the iris incarceration of the lens capsule or of the iris in the wound, adhesion of the hyaloid membrane to the wound and anterior synechia of an iris pillar. Other factors postulated are increased formation of aqueous resulting from traction during needling and retained lens cortex or vitreous which blocks the angle and causes tension and glaucoma secondary to iritis or uveitis.

It is well known that when the lens is in situ occlusion of the pupil, with or without iris bombe may cause secondary glaucoma. Moreover this form of secondary glaucoma can be relieved if communication is re-established between the chambers by transfixion of the iris or by iridectomy, unless the angle has become permanently closed in long standing cases.

A similar cause for glaucoma is postulated in eyes in which the lens is absent or dislocated. The type of secondary glaucoma is discussed and illustrative cases are presented. Four types which are very similar are presented because the mechanism of the block is slightly different in each case.

In all 4 types shallowing of the anterior chamber may result in mechanical closure of the angle. Except for cases in which leakage occurs at the wound, there is no cause for progressive shallowing of the anterior chamber in an aphakic eye (or one in which the lens is partially or completely dislocated backward) other than lack of free communication between the posterior and the anterior chamber. Typical iris bombe, when present, immediately indicates a blocked pupil.

A dense pupillary membrane may be so firmly adherent to the iris peripheral to the pupillary border as to prevent a general shallowing of the anterior chamber. In doubtful cases of this kind transfixion of the iris can be used as a diagnostic procedure. If a pupil is completely blocked with a membrane (partly or wholly inflammatory), discission should be preceded by peripheral transfixion of the iris.

Glaucoma does not develop after intracapsular extraction unless the prolapsed vitreous completely

nystagmus occurs but is directed toward the operative side, accompanied by swarming or swaying or the less frequent whirling sensation of the body and objects. On looking straight ahead slow oscillatory movements synchronous with the pulse occasionally associated with nystagmus of the head and accentuated by pressure on the carotid artery of the ipsilateral side are seen instead of the jerky movements of genuine nystagmus. Spontaneous nystagmus usually disappears in 3 or 4 days and the dizziness is gone in a week except on sudden movements of the head particularly toward the operated ear. By the fifteenth postoperative day all traces of the symptoms have disappeared.

In comparing labyrinthine findings subsequent to fenestration with those subsequent to surgical injuries of the semicircular canals, it was found that in the latter dizziness is immediate and more marked vomiting is outstanding lasting for 4 to 5 days and the spontaneous horizontal and rotatory nystagmus invariably runs toward the uninjured side and disappears in from 1 to 4 weeks. Surgical injuries are always followed by infection with impaired hearing and the nystagmus differs in duration and direction from that following fenestration hence it is significant to note if the nystagmus is directed toward the side of the fenestration and decreases in a period of a few days which is simply caused by the opening of the perilymphatic space. If the nystagmus is directed toward the other side and continues for more than a week, it is probable that an infection of the fenestra has occurred and the operation will not be successful. Slow oscillatory movements of the eyes and nystagmus of the head are not common symptoms of surgical injury of the horizontal semicircular canal but occur in the presence of pathologic fistulas secondary to infection of the tympanic cavity or in syphilitic infection of the internal ear. A hypothetical explanation of the oscillatory movements of the eyes is that they are due to the fact that hyperemic granulation tissue containing pulsating blood vessels continually pushes the endolymph to and from the ampulla. The vascular symptoms do not indicate an infection of the fenestra.

In the fistula test, made in 24 cases from 5 weeks to 14 months after operation the cotton applicator yielded positive results more frequently than did compression and aspiration of the Politzer bag. The cotton applicator is inadequate and does not permit conclusions concerning the motility of the labyrinthine fluids and the status of the sensorial organs within the internal ear. This was shown by Uffenorde who showed that probing a fenestra may elicit nystagmus even in instances in which the turning and caloric tests no longer yielded positive results. If the fenestra responds to probing but not to air compression the results as far as hearing is concerned are poor and for this reason the fistula test should be performed with the Politzer bag and not with a cotton applicator. The location of the fistula on the horizontal semicircular canal does not exert any influence on the results of the fistula test. A positive

compression test does not necessarily indicate that the aspiration test will also produce the fistula symptom. The atypical results of the fistula test do not necessarily depend on inflammatory changes in the perilymphatic space.

Pulaski Edwin J. and Matthews, Charles S.: Streptomycin in Surgical Infections: Otitis Externa, Otitis Media, Mastoiditis, Brain Abscess and Meningitis. *Arch. Otol.* Chic. 1947 45 503

The authors present the results obtained with the use of streptomycin in a group of 41 patients with otitis externa, otitis media, mastoiditis, brain abscess, and meningitis.

In 5 patients chronic otitis externa due to susceptible gram negative bacilli and gram positive cocci unaffected by other agents responded favorably to the topical administration of a solution of streptomycin. Of 13 patients with chronic otitis media of mixed bacterial cause 11 were benefited by the topical application of streptomycin. A patient with mastoiditis and lateral sinus thrombosis recovered after surgical intervention and adjuvant administration of streptomycin. Recovery occurred in 7 patients and death in 1 patient with solitary brain abscess who were treated by surgery in combination with streptomycin therapy. Streptomycin, it is believed is a valuable addition to the therapeutic armamentarium for infections of the ear, meninges, and brain when the infections are due to susceptible organisms.

NOAH D. FABRICANT, M.D.

Reading, Philip: Recurrent Mastoiditis. *Guy's Hosp. Rep., Lond.* 1946 95 79.

A consideration of the operative findings in the temporal bones of patients with 'recurrent mastoiditis' prompted the writing of this article. Experience with this complication has led the author to the conviction that the cortical mastoidectomy of Schwartz is by its clinical results good or bad, is based on unsound surgical principles. In his opinion, no matter what after treatment is adopted or how successful it may be one cannot ignore the fact that the operation is based on unsound surgical principles. A cavity of varying size is left partially or completely clothed with epithelium. This cavity is continuous with the middle ear and eustachian tube and so is open to reinfection at any time. Perhaps the day is not far distant when with the advance of systemic penicillin therapy the cortical mastoidectomy may be relegated to history.

NOSE AND SINUSES

Burtuff Samuel: Evaluation of Diagnostic Methods Used in Cases of Maxillary Sinusitis, with a Comparative Study of Recent Therapeutic Agents Employed Locally. *Arch. Otol., Chic.*, 1947 45 516

The present article is based on a study of 100 cases, to evaluate the methods of diagnosing maxillary sinusitis. A comparison of the therapeutic value

of several solutions now in use for irrigating the sinuses was also made. A nonbactericidal and nonbacteriostatic agent, such as an isotonic solution of sodium chloride, used locally proved just as effective in bringing about resolution of the sinusitis as did the sulfathiazole and penicillin solutions, also used locally. Neither the sulfathiazole nor the penicillin in solutions proved to be of the value anticipated in the local treatment of maxillary sinusitis.

MOUTH

Alexander, John E.: Early Treatment of Maxillo-facial Battle Casualties; A Résumé of 421 Cases. *Arch. Otolaryng.* Chic., 1947 45 637

This is a résumé of the cases seen by a plastic maxillofacial surgery team of an auxiliary surgical group attached to one of the United States armies. It covers the period including the Battle of Normandy, the Battle of France, the Battle of the Ardennes, the Battle of the Rhineland and the Battle of Central Germany. The work was done in evacuation hospitals.

It is not a detailed account of all the work done nor is it a detailed description of individual cases. It is intended only to call attention to certain principles and to mention in summary fashion some of the more interesting and unusual aspects.

The statistical study covered a total of 421 operative cases. There were 3 deaths, which made the mortality rate 0.71 per cent.

Breaking the collection of cases down into an anatomic and descriptive classification presented a problem, hence it was decided to employ as nearly as possible a grouping related to the operative treatment which is shown in a table listed under 15 different headings. The cases include those subjected to split skin grafting, those requiring some type of plastic procedure such as sliding flaps, and those requiring repair of auricular defects.

No distinction was made between face wounds that were superficial and those that were deep so far as the decision to close them was concerned, provided certain conditions were met. These were drainage when indicated, absence of gross infection and adequate toilet of the wound.

The entire aim in this work has been to accomplish as much as possible at the first operation, with reconstructive procedures when this was practicable but the important principle of not doing any operation which if unsuccessful would preclude the final successful outcome of plastic surgical procedures to be done in the zone of the interior was kept in mind.

In a word it is felt that any one stage flap operation that is completed in that stage is capable of being accomplished in the first treatment of maxillofacial battle injuries. No stage of a plastic procedure involving another operative site should be started at this period in the treatment.

Sulfanilamide or penicillin were never applied to any wounds which were to be closed. However when

wounds were to be left open, penicillin powder was lightly sprayed on all raw surfaces.

Penicillin was used routinely in all cases in doses varying from 30,000 to 40,000 units, and was administered every 4 hours for 3 or 4 days.

This article is long and comprehensive and is illustrated with numerous figures and roentgen films. No definite summary can be made except to say that the field of maxillofacial surgery in war time has been thoroughly covered.

JOHN F. DILLON, M.D.

Young, Morris N.: Maxillofacial Fractures—187 Cases: Experiences with a Hospital in Cassablanca, Oran, and Marseille. *Arch. Otolaryng.* Chic., 1947 45 668.

This article is a historical treatise on the activities of the 69th Station Hospital during the African, Italian, and Southern France campaigns, and summarizes the histories of 187 cases of maxillofacial fractures. The routine treatment guide is submitted.

The general principles and procedures to be followed in the treatment of maxillary and mandibular fractures may be formulated as follows:

In early stages

1. Vigorous antishock therapy
2. Decision for tracheotomy not to be influenced by excessive conservatism.
3. Liberal use of penicillin and sulfonamide compounds.
4. Avoidance of barbiturates for general anesthesia.

In later stages

1. Adequate diet. Dietitians should be made "liquid jaw diet" and "soft jaw diet" conscious.
2. Careful application of suitable intracranial splinting devices, or if indicated, external pin fixation as modified for use in fractures of jaws.
3. Minimum period of immobilization of jaws.
4. Active and meticulous attention to oral hygiene.
5. When considerable avulsion of tissues has occurred early thin skin grafts may be used for protecting the surface pending reconstructive procedures.

In cases of osteomyelitis

1. Minimum sequestrectomy and curettage, through ample incision, after an initial period of preoperative re-establishment of normal metabolic levels.
2. Local and parenteral administration of penicillin.
3. Fixation of fracture by the most ample means.

JOHN F. DILLON, M.D.

Goodell, Ralph E. and Flanders, Sarah E.: Successful Primary Repair of Lacerated Stenson's Duct. *Surgery* 1947 31 803.

The authors state that the anatomic location of Stenson's duct makes it subject to injury in deep wounds of the cheek. As failure to repair the duct results in a salivary fistula with many distressing symptoms, it is imperative to attempt to reapproximate the divided ends at the initial débridement.

Eight cases of primary suture of Stenson's duct have been recorded in the literature. The methods used varied but slightly. Success of the procedure seems to depend on the use of an inlying dowel firmly fixed in place at the time of early débridement. It is the purpose of the authors to give a brief review of the anatomy of Stenson's duct also to report another case of primary suture of the parotid duct and show the success of the procedure with accompanying pictures of the patient and sialograms taken 6 months following the operation.

The authors then give a brief discussion of the anatomy of Stenson's duct.

The case report was that of a 35 year old man who was admitted to the Bellevue Hospital on December 31, 1944 with multiple lacerations of the face and hands having been assaulted with a sharp instrument about an hour prior to admission. There was a deep laceration 6 cm. in length extending obliquely from over the zygoma at a point about 3 cm. anterior to the tragus of the left ear almost to the midpoint of the body of the mandible. The buccal mucosa was intact. He was unable to move the left side of the face. There was also a 2 cm. laceration over the lateral margin of the left eye and a 2 cm. laceration of the base of the nose. A 6 cm. laceration extended across the knuckles of the third to the fifth fingers of the left hand with division of the tendons and the laceration had penetrated directly into the bony substance partly severing the metacarpal heads. The patient had a flexion deformity of the third to the fifth fingers due to a pre-existing Dupuytren's contracture. A similar deformity involved the fifth finger of the right hand and there was a superficial laceration of the right thumb. The remainder of the examination was within normal limits except for an old upper right rectus scar.

Two hours after admission débridement and suture of the multiple lacerations were performed under sodium pentothal anesthesia. The lacerations of the tendons on the left hand were also repaired. All wounds were uncomplicated except for the one in front of the left ear where exploration revealed complete division of Stenson's duct in the masseteric portion and division of the three terminal branches of the facial nerve. After careful cleansing and irrigation of the wound and removal of all devitalized tissue, the masseter muscle was sutured and an attempt was made to approximate the severed ends of the facial nerve branches but the smallness of the branches made approximation doubtful. However the proximal end of the severed duct was easily identified and the distal end was located by passing a small urethral catheter through the orifice in the mouth. When the catheter emerged in the laceration, it was passed into the proximal segment of the duct. The two ends were then sutured over the catheter with interrupted sutures of fine black silk. Primary closure of the wound was carried out. The catheter was taped securely to the lower lip to hold it in place and a dry sterile dressing was applied.

Postoperatively the patient was given nothing by mouth and oral hygiene was maintained. He had a slight elevation of temperature for 4 days, spiking to 103° F. on the fifth and sixth days with subsequent return to normal. On the fourth postoperative day there was slight swelling over the left parotid gland. The wound however was clean. There was a slight reaction about the orifice of the duct in the mouth. No flow of saliva was noted. The catheter was removed on the fifth postoperative day. The patient was fed parenterally until the sixth day when he was placed on a full fluid diet. He was given a soft diet on the seventh day and it was tolerated well with no swelling or pain in the region of the left parotid gland. A free flow of saliva was noted from the stoma of Stenson's duct. Because of the left facial paralysis, a tarsorraphy was performed on the twelfth day but the operation was unsuccessful. He was discharged from the hospital on the eighteenth postoperative day. The patient was contacted 6 months later at which time the sialograms were taken. There was no fistula, swelling or tenderness of the parotid gland and the sialogram showed a normal pattern with no stenosis of the duct.

The original article presents pictures of the patient 6 months postoperatively and reproductions of the sialograms.

The authors discuss the variants in the form of treatment of this and other cases reported in the literature. Constant factors were that débridement and suture were carried out as soon as possible after injury and an inlying dowel was used in every case but one. The type of dowel varied and it did not seem to make any difference which kind was used. Those that have been used have been stiff iodine catgut, silkworm gut, urethral catheters, fusiform bougies, and several others. Successful results were obtained in each instance which suggests that the type of dowel is not important. The use of the dowel is to maintain, but not to occlude completely the lumen of the duct until healing has occurred. In addition the anatomic structure of the duct probably contributes to success as its thickness allows accurate and substantial placement of the sutures. The type of suture used seems to make no difference. Catgut silk, and cotton have all been used with success. Some cases have been closed with drainage and others without.

It, therefore appears from this report and other reports appearing in the literature that salivary fistula can be prevented by successful primary suture of Stenson's duct. WILLIAM A. ABROON, M.D.

NECK

Ward Robertson: Malignant Goiter. Lessons to be Learned from a 36 Year Follow Up. *West J Surg* 1947 55 383

This report is based upon the study of 170 cases of cancer of the thyroid gland. It is believed that the usual 5 year follow-up of cancer is not adequate

when dealing with malignant goiter. An 8 to 10 year remission of growth is not unusual after operation alone or with roentgen therapy. Nodular goiter and malignant goiter must be considered together for it is believed that nodular goiter is the breeding ground of malignancy. Malignancy in solitary adenomas was found in 15.6 per cent of 96 cases. Children under 15 cannot be excluded when malignancy in a nodular goiter is considered. A table showing the incidence in nodular goiter by sex is presented. In females, malignancy was present in 3.4 per cent and in males it was present in 1.2 per cent of nodular goiter.

The author suggests that a subtotal lobectomy should be performed for all solitary tumors in nodular goiters in males and children. When tumor thrombus is demonstrable in the lateral veins a sacrifice of the deep jugular vein is indicated. Metastatic deposits are removed by block dissection. One recurrent laryngeal nerve was sacrificed when it was imbedded in malignant tissue. X-ray therapy of bulky papillary tumors may cause sloughing. Radon seeds have been implanted in irremovable tissue. In the 3 groups listed the incidence of malignancy was shown to be between 1.2 and 24 per cent. Radioactive iodine was used in 10 cases. In 7 of these cases there was no measurable pickup of radioactive material by the malignant tissue. In 3 cases, there was a slight pickup and in 1 case, there was unusual deposition of radioactive material in the metastases. This leads one to believe that a tumor may be entirely eliminated or its growth may be arrested. It appears that adequate and early surgery is still our best prospect for the cure of malignant goiter.

RICHARD J. BENNETT, JR., M.D.

Hare, Hugh, F.: Cancer of the Thyroid. *Surg. Clin. N. America*, 1947, 27, 56.

The classification of thyroid tumors according to Shields Warren is accepted as a basis for the present study. This is as follows:

Benign tumors (1) adenomas—embryonal fetal simple (Hürthle cell) colloid and (2) papillary cystadenomas—originating from thyroid or originating from aberrant thyroids.

Malignant tumors (Group I) tumors of low or potential malignancy—adenomas with papillary cystadenoma with blood vessel invasion originating in either the thyroid gland or in aberrant thyroid tissue (Group II) moderately malignant adenocarcinomas—papillary, alveolar, Hürthle cell, and (Group III) tumors of high malignancy—small cell carcinomas (compact type, diffuse type), giant cell carcinomas, epidermoid carcinomas, fibrosarcomas, and lymphomas.

Between the years 1926 and 1936 240 patients with malignant tumors of the thyroid were treated. These were subsequently observed for 5 years or more. 120 of these were of Group I, 77 of Group II and 53 of Group III. Three were sarcomas.

Tumors of low or potential malignancy (Group I) usually developed from pre-existing single nontoxic

adenomas. The etiology of the more highly malignant tumors (Groups II and III) could not be determined.

Lateral aberrant thyroid tissue occasionally becomes malignant. Histologically such tumors are papillary cystadenomas and have some of the characteristics of thyroid tissue. Diagnosis rests on the known relationship of these tumors to aberrant thyroid tissue.

Tumors of Group I usually have a duration of from 1 to 5 years. Occasionally there is rapid growth during the last week or month. The preoperative diagnosis was often simple adenoma.

Tumors of Groups II and III are usually easily diagnosed. There is usually evidence of venous compression and a hard fixed infiltrating mass. There may be stridor. Thyroiditis may be confused with early malignancy. The distinguishing feature is that usually with thyroiditis the gland remains symmetrical, whereas with malignancy symmetry is lost.

An indication of malignant degeneration of an adenoma is the change from moderate firmness to induration. However a sudden and painful increase in hardness is more likely to be due to hemorrhage into an adenoma.

Other important signs of malignancy are attachment of the gland to prethyroid muscles and bone.

Toxic adenomas are rarely the site of malignant degeneration of 7 cases encountered in a 10 year period. 4 occurred in patients with multiple colloid goiters and toxicity.

Surgical removal is indicated for all malignancies of the thyroid. Although the low or potentially malignant group can be completely removed surgically radiation treatment following surgery is advised because of frequent recurrences and because these tumors are radiosensitive.

With the more malignant tumors, it is essential that adequate radiation should be delivered to the entire field by crossfire technique with one portal on each side of the neck and one in the midline. A dose of 2,000 roentgens measured in air is given to each portal making a total of 6,000 roentgens for one series of treatment. The daily treatment is 150 roentgens for each portal, except for debilitated patients who receive 100 roentgens. The following factors were used: 300 k.v.p., 30 ma., 24 roentgens per min., 1 mm. of copper, 1 mm. of aluminum, 50 cm. distance portal from 7 to 10 sq. cm., and half layer value 1.3.

CURTIS H. TAYLOR, M.D.

Labey, Frank H.: Tumors of the Neck. *Surg. Clin. N. America*, 1947, 27, 486.

Tumors of the neck are discussed under three headings: midline tumors, solitary lateral tumors, and multiple tumors of the neck. All midline tumors of the neck are of thyroid origin. Rarely there is complete failure of the thyroid to descend and a lingual thyroid results. These thyroid glands require removal only because of pressure symptoms after their surgical removal the patient will be completely

eye. A single instillation of dimercaprol solution or ointment within from 2 to 5 minutes after exposure to lewisite effectively prevents the development of serious ocular lesions. The method by which the drug works is described.

HUNTER H. ROMANOW, M.D.

Godtfredsen, E.: Ophthalmoneurological Symptoms in Connection with Malignant Nasopharyngeal Tumors. *Brit J Ophth.*, 1947 1 78.

The author indicates that the ophthalmoneurological symptoms in connection with malignant nasopharyngeal tumors occur both earlier and to a greater extent than is generally known, and that the ophthalmological symptoms predominate chiefly as ophthalmoplegia with or without attending trigeminal neuralgia. Patients suffering from this condition frequently will go first to the ophthalmologist which puts the diagnosis up to him.

HUNTER H. ROMANOW, M.D.

Gordon, D. M.: Ocular Sporotrichosis: Report of a Case. *Arch. Ophth.*, Chic., 1947 37 56.

The author reviews the literature on ocular sporotrichosis and reports a case in his own experience. He points out that 48 cases have been reported in the literature. Thirty-four were primary and 15 were secondary to involvement elsewhere in the body.

The following parts were affected: the eyelids in 17 cases; the conjunctiva in 10; the lacrimal sac in 2; the conjunctiva and lacrimal apparatus in 1 case; the eyebrows in 1; the intraocular tissues in 5 cases; the orbit and eyelids in 5; the cornea in 3; the limbus in 1 case; the uveal tract in 1; and the lacrimal canal in 1. Ten of the cases occurred in the United States; most of the others occurred in France.

The disease responds to potassium iodide. A saturated solution is administered, beginning with 10 drops 3 to 4 times a day which is increased by 5 drops per dose per day until the limit of tolerance has been reached. Treatment is continued for several weeks. Iodides stimulate the fibroblastic elements to proliferate and to encapsulate the sporotrichum.

JOSIEVA ZUCKERMAN, M.D.

Samuels, B.: Proliferation of Lens Epithelium. *Am. J. Ophth.*, 1947 3 1.

The author believes that a strict differentiation between ectoderm and mesoderm cannot always be made. It is possible for the epithelial cells of the lens, when irritated to lay down a tissue, the anterior subcapsular cataract, that has physical qualities more of mesoderm than ectoderm. Following extracapsular cataract extraction, there may be a proliferation of germinal cells in Soemmerring's crystalline swelling or of the subcapsular epithelium to form the pearls of Elschmig.

The purpose of this article is to summarize the proliferation of the epithelial cells of the lens in 185 cases of nontraumatic cataracts. This did not include cases which may have had a rupture of the capsule since the author did not wish to have any in which other

cells entered the discussion. He does not believe that cells pass through the lens capsule. He found that the greatest proliferation occurred in the cases with corneal scars and detachment of the retina and in cases of spontaneous iritis. The lenses that showed the least proliferation were found in the cases of intraocular tumors and glaucoma. He found that the proliferation of anterior capsular epithelium (subcapsular cataract) was most commonly central and that this was due to the absence of the protective influence of the iris. Subcapsular cataracts may also be excentric, equatorial, and posterior.

He found three types of anterior polar cataracts: the widespread type with an undulating anterior surface, the pyramidal type, and the thin fibrous type with sharp wrinkles in the capsule. He believes that they are made up of an epithelial connective tissue. The pyramidal cataract was most frequently associated with corneal ulcers and was thought to be due to a short concentrated exposure to toxins. More extensive proliferation was characteristic of the cases of spontaneous retinal detachment. When the germinal cells have disappeared or have fallen away from the capsule, the anterior cells may take their place and grow backward to form one continuous layer of cells. Occasionally the lens epithelium will attempt to repair an area of necrotic cells but being unable to do so forms a homogeneous mass about this area. The proliferation of germinal cells usually occurred in liquefied lenses and was characterized by large bladderlike cells at the equator or along the posterior capsule. They frequently merged into large cystic spaces. Whenever a subcapsular cataract was found at the equator or posteriorly it was considered to be a product of wandering anterior subcapsular cells.

Occasionally the capsular cells elongated, in 3 cases drawn were found under the capsule and in 2 cases there were no epithelial cells. In 1 case the whole germinal zone was detached and floated about in the liquefied cortex.

ROBERT H. JOHNSON, M.D.

Martin-Jones, J. D.: Uveal Sarcoma. *Brit. J. Ophth.*, 1946, 30, 3, Supp.

The author has written a monograph on the relatively rare condition of intraocular sarcoma. He believes that trauma and heredity do not play a part in the etiology but that areas of pigmentation, pigmentary disturbances, areas of choroiditis, and hemorrhages in the macular region are factors. These tumors seem to be equally distributed between the two sexes. In this series the average age of incidence was 51.9 years, the youngest patient being 14 years and the oldest 87 years. The author found that 38.5 per cent of the patients did not come for examination until their vision was nil although 2.5 per cent still had useful vision.

He uses the customary procedure of dividing the course of an intraocular sarcoma into four stages: the quiescent stage, the stage of glaucoma, the period of perforation into the orbit, and the stage of generalized metastasis. The last stage may occur at any time.

myxedematous. These tumors can often be successfully removed through the mouth. Thyroglossal cysts and sinuses are another form of midline tumor. Not only must the cyst be completely excised but the central portion of the hyoid cone and a portion of the base of the tongue must be completely removed to avoid recurrences. Some adenomas of the thyroid are midline tumors. The author is of the opinion that all discrete adenomas of the thyroid should be removed because of the danger of malignant degeneration.

The treatment of single discrete laterally located tumors of the neck is important because of the fact that not a few of them are or become malignant. The most common tumors in this location are the branchial cysts. They empty into the pharynx close to the tonsil. Below the level of the digastric muscle these cysts and sinuses are superficial in position. The best method of treating branchial cysts and sinuses is by their surgical removal through multiple small incisions. The next most common laterally located tumors of the neck are lateral aberrant thyroid tissue. They may be single discrete tumors or they may be multiple. When discrete a diagnosis is only possible upon microscopic examination. They also are superficial in position. In the 47 patients seen with lateral aberrant thyroids 9 were malignant and 2 patients have died. The tumors are highly radio-sensitive and radical removal followed by high volt-

age x ray therapy gives good results. One of the rare tumors of the neck is a tumor of the carotid body. These tumors cannot be moved downward because of the fact that their descent is limited by their origin in the carotid notch. Also they tend to grow inward and are deeply located as contrasted to the previously mentioned tumors. When these tumors surround the three vessels so that ligation of all these structures would be required for the removal of the tissue, the author believes that the danger of malignancy is less than the danger of the ligations. In such a situation he does not remove the tumor. Figures as to the percentage of malignancy in these tumors vary from 50 to 80 per cent. Neurofibromas may also be found as lateral single neck tumors.

When multiple tumors and cysts of the neck are present, diagnosis is more difficult. Tuberculous cervical adenitis is still occasionally seen and is best treated by irradiation. Hodgkins disease of the glands of the neck must always be considered in the presence of multiple neck tumors. Multiple neck tumors may result from malignant metastases, adenomas of the thyroid and lateral aberrant thyroid tissue. The one outstanding feature which distinguishes intrathoracic goiter from most other mediastinal tumors is the fact that it ascends and descends with swallowing. The only other tumors which do this are certain benign esophageal tumors.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

War Surgery Supp. No. 1. Wounds of the Head.
Brit. J. Surg. 947 Supp. 1

In 1944 the British Journal of Surgery devoted one issue to the subject of penicillin, at a time when considerably less was known about the total possibilities and limitations of the drug than is true today. However that volume still stands as a sound treatise on the subject. The same journal has now devoted an issue to the subject of wounds of the head, dealing with the British military experience in neurosurgery during the period from 1939 to 1945. Again, it is likely that the subject of military neurosurgery will not soon again be covered in such a comprehensive and instructive manner.

The experiences reviewed in the present volume cover all the various theaters of the war and all the major campaigns and battles. The bulk of the collected papers are from the Army, though the Royal Navy is also represented with its smaller number of casualties.

A fitting introduction has been written by Geoffrey Jefferson, whose broad experience as one of England's senior neurosurgeons bridges the two great world wars. The highlight of this memorable collection however is the second article, that by Hugh Cairns, which deals with the organization and early development of the neurosurgical organization of the British military, the evolution of the treatment of the uncomplicated vertex wound of the brain, special types of brain wounds, infections, the specific neurological signs of head wounds, after care, the special factors of success and failure in treatment, and a consideration of other outstanding problems. From this paper alone the reader may appreciate the value of highly trained mobile, closely co-ordinated teams of surgical specialists working near the front after the manner of the British Mobile Neurosurgical Units. From this the American Army Medical Corps could learn and profit much. The British were realists. The time came when they found themselves increasingly poor in man power and the saving of life, time, transport and other effort, with the early return of the patient to duty was with them a much more vital concern than apparently was true in our own organization.

The volume is profusely and well illustrated. The colored illustrations of Shorstein's article are remarkably good and tell the story even without the text. The rather stylized format of all the articles makes reading pleasant and easy to remember. The subjects of infection, complications, and chemotherapy are considered from every angle and in most instances case reports, where used effectively drive home good points. Ascroft's interesting article on his survey of 662 fatal head wounds is included.

Also included are several papers which were presented in their original form at the neurosurgical meetings in Rome and Florence in February and March of 1945 and many American neurosurgeons who were present at those meetings will recall with interest those days in association with a most stimulating group of British doctors.

This remarkable volume is recommended to all military administrators, members of the American Army and Navy Medical Corps, and neurosurgeons in general. It should be compulsory reading for all medical students before graduation.

JOHN MARTIN, M.D.

Govan, Clifton D., Jr., and Walsh, Frank B.: Symptomatology of Subdural Hematoma in Infants and in Adults: Comparative Study with Particular Reference to the Ocular Signs; An Observation Concerning the Pathogenesis of Subdural Hematoma. *Arch. Ophthalm., Chic.*, 947 37 701

The symptomatology of subdural hematoma in infants and in adults has been discussed in considerable detail by the authors. A reported series of 30 infants and 1 older child of 8 years was compared with an adult group of 54 patients. The point was stressed that there was only 1 patient in the age group of "two to twenty years."

Of the infants, 21 were males and 15 were females. Nineteen of the 37 infants and 49 of the 54 adults had a history of trauma.

The nutritional state in 14 of the infants was poor. No accurate evaluation was made in the adults.

Convulsions were present in 18 of 35 infants, in contrast to the adults, only 2 of whom had convulsions.

Vomiting was present in 18 of the infants and in 16 of the adults.

Twenty infants were drowsy with retained irritability to stimulation. Only 2 of the infants were reported as alert. Drowsiness was a very frequent finding in the adults.

Bulging of the fontanelle was present in 16 of 28 infants with an open fontanelle. One third of the infants had an elevated temperature. In the adults no accurate figures on this point were available.

The hematoma was unilateral in 51 of 54 adults hemiparesis was present in 22 in 17 weakness was contralateral, and in 4 ipsilateral.

The spinal fluid in the infants invariably contained blood or was xanthochromic. In the great majority of adults, the spinal fluid was normal.

Papilledema was estimated as 50 per cent in adults, although in this series only about 17 per cent of both adults and infants were reported as showing papilledema. The type of papilledema in adults is similar to that observed in cases of tumor, there may or may not be retinal hemorrhages of nerve fiber layer type

In infants almost invariably subhyaloid retinal hemorrhages are visible.

In adults unilateral dilatation of the pupil is frequently found on the side of the hematoma. In frequently the pupil contralateral to the lesion was dilated. Dilatation of the pupil has been attributed by Reid and Cone and Woodhall, and their associates, to herniation of the hippocampus of the medial aspect of the temporal lobe and midbrain through the tentorium. As a result of such herniations pressure was produced on the homolateral third nerve with development of an internal ophthalmoplegia which may be associated with ptosis.

Sixth nerve palsy was present unilaterally in 3 adults and bilaterally in 1 adult. Nystagmus was present in only 3 adults. Conjugate deviation of the eyes away from the side of the lesion was present in 2 adults. Visual field changes were infrequent.

The authors have made the observation that in infants the hemorrhage is almost always bilateral and the spinal fluid bloody in contrast to the situation in adults in whom it was a very infrequent finding. It is noted also that frequently in infants there is no history of trauma whereas in adults there is almost invariably a history of trauma.

Anatomical studies show that in the infant the dura and delicate arachnoid membrane are easily separated from the vessels and pia mater close to the midline. These veins in emptying into the longitudinal sinus, are relatively unsupported for distances varying from a few millimetres to one centimeter which the authors feel is an important point in the frequency of bilateral bleeding in infants as well as the frequent findings of blood in the spinal fluid.

In contrast to this condition it is pointed out that in adults the dura and the arachnoid membrane are firmly bound together in the region of the longitudinal sinus. This attachment of the arachnoid to the dura is formed by masses of fibrous tissue forming the base of arachnoid villi (pachyionian granulations).

HOWARD A. BROWN, M.D.

Bingham John A. W.: Causalgia of the Face
Brit. M. J. 1947 1: 804.

The author describes 2 cases of causalgia of the face. The condition was successfully treated by dividing the sympathetic chain below the superior sympathetic ganglion and by resecting the lower half of the ganglion.

The first case was that of a 28 year old Indian who had received a small penetrating wound of the right cheek. X ray examination revealed a small metallic fragment under the base of the skull in the region of the foramen ovale. Burning pain developed immediately in the right side of the face and was still present when he was seen a year later. The pain was described as continuous and involved all three divisions of the trigeminal nerve. There was also marked hyperalgesia of the skin in the same area and the pain was aggravated by warmth, with catting, or with much talking. A procaine-alcohol injection of the stellate ganglion gave immediate

temporary relief of the pain but 3 weeks following injection the facial pain and tenderness recurred. Under local anesthesia the right superior sympathetic ganglion was exposed. The chain was divided and the lower half of the ganglion was excised. The facial pain and tenderness were again completely relieved and there was no sign of recurrence 3 months later.

The second patient also received small penetrating wounds of the left side of the face and head. Three months following injury he noted continuous burning pain confined to the maxillary division of the trigeminal nerve. X rays showed multiple foreign bodies in the scalp and left parietal area and left temporal fossa. As in the first case a marked hyperalgesia of the skin of the cheek was present. A procaine-alcohol injection gave immediate but temporary relief of pain and later the lower half of the superior sympathetic ganglion and a portion of the sympathetic chain were excised. Facial pain and tenderness were relieved immediately.

A brief discussion of the etiology and mechanism of production of causalgic pain is presented. The author believes that sympathectomy relieves causalgic pain by interrupting the sensory pathway.

HOWARD H. LANDER, M.D.

PERIPHERAL NERVES

Davis, Loyal Martin John; and Perret, George
The Treatment of Injuries of the Brachial Plexus. *Ann Surg* 1947 135: 647

The authors state that injuries to the various parts of the brachial plexus may be of the same general nature regardless of whether the patient is of civilian or military status. Blunt injuries, such as direct blows or traction and attenuation of the plexus, occurred in 17 of their 47 patients, whereas the other 30 patients suffered open injury of the plexus, either through gunshot or stab wounds.

In the blunt closed injuries the funiculi are torn apart not cut at any one particular level as in the open injuries, and such ruptures may occur at any point from the origin of the roots at the spinal cord to the most distal part of the nerve trunks. The resulting lesions are those of complete or incomplete anatomic or physiologic lesions which should not be classified as "upper" or "lower" types. The record of the examination must show that the lesion has been located by a careful examination of the affected muscles and the sensory patterns. By no other method can accurate diagnosis or final evaluation of the residual lesions be made.

Admittedly injuries of the brachial plexus are difficult of evaluation as to the probable extent of spontaneous recovery and especially is this true in the blunt injury. Such recovery may progress over months and years. Obviously the results of surgical treatment of such lesions could never be as good as they are in simpler peripheral nerve injuries. Rarely is end to end suture possible, and for that reason the use of nerve grafts should be

of distinct value when gaps occur after the open type of injury. Neither type of injury should be denied the benefit of surgical treatment when, with persistent physical therapy the progress of recovery has reached a stand still. Neurolysis with careful removal of all constricting bands and scar tissue should be followed by a regimen of physical therapy planned for many months. Estimations of the recovery of function in all peripheral nerve surgery must be based upon the recovery of sensation in isolated areas of supply and upon the recovery of movement in muscles whose action cannot be imitated by supplementary movements.

JOHN MARTEL, M.D.

Amnersten, Shante: Studies on the Scalenus Anticus Syndrome. *Acta chir scand.*, 1947 95 419.

The author reviews the mechanism of the scalenus anticus syndrome as previously given in numerous articles published in this country and describes a method of measurement of the transverse process of the seventh cervical vertebra. He has studied these measurements in 400 roentgenograms of the neck, and has compared them with the length of the transverse process of the first thoracic vertebra thus establishing an index which he believes will be of help in determining those conditions that may fall into the category of the scalenus anticus syndrome and be benefited by surgical measures.

In conclusion the author states that scalenotomy alone is sufficient in those cases in which compression of the nerve is brought about by pressure of the scalenus muscle upon the costotransverse process of the seventh cervical vertebra. If the transverse process is enlarged—even without a true rib—such compression is likely to occur and this enlargement was present in the majority of the cases reported in the present article.

Such compression also may give rise to vasomotor disturbances in addition to those of purely neurogenic character.

HOWARD A. BROWN, M.D.

Björkstén G af Suture of War Injuries to Peripheral Nerves. Clinical Studies of Results. *Acta chir scand.*, 1947 95 Supp. 19.

The author has studied a series of 756 Finnish war casualties in whom nerve sutures were performed for a postoperative period extending from 6 months to 5 years. In judging the amount of recovery he considered only return in motor function. Of 756 nerve sutures, only 13 were primary sutures performed immediately after the injury in a field hospital, the other 744 were secondary sutures performed in a general hospital. The primary sutures became infected in 50 per cent of the cases and their recovery was not satisfactory. The positive results in secondary sutures depended only to a small extent on the interval between trauma and operation. Among the patients operated upon during the first 3 months after the injury the results were positive in 89.6 per cent, and this number gradually decreased to 71.7 per cent for patients operated upon later than

Nerve	Number of cases	Percentage of qualitative results			Post-operative results per cent	Long-term results per cent
		Good	Medium	Poor		
Brachial Plexus	6	16.7	23.3	60	100	
Musculocutaneous	30	30			100	
Radial	185	8	41.5	50.5	95.8	
Median	96	9	44.8	46.2	93.6	6
Ulnar	82	9.9	43	47	99.6	9.4
Femoral	30	30	50		100	
Sciatic (tibial portion)	84	23.8	52.4	23.6	79.8	30
Sciatic (peroneal portion)	84	3	17.9	44.0	37	47
Tibial	9	2	66.4	31.6	94.7	13
Peroneal	15	20.7	45.3	33.3	73.3	66.7
	73	16.7	30.3	53.0	85.1	24.1

a year after trauma. However qualitatively much better results were obtained when the nerve was sutured early and the failures outnumbered the satisfactory results when the nerve suture was performed later than 9 months after injury.

Signs of motor recovery were observed earlier in the upper than in the lower extremity but the tibial and the radial nerves were observed to require the shortest period of regeneration. The author also found that motor recovery was much delayed in low or distal lesions as compared to more proximally situated lesions. In no instance did he observe any return of function in the small muscles of the foot, and reinnervation of the small hand muscles was usually slow and incomplete. He never saw complete restitution of function in any of them even 5 years after operation. The above table shows the results obtained 1 year after suture.

The age of the patients played only a minor role. The author states, however, that the 50 oldest patients (between 47 and 51 years of age) showed much poorer results than the 50 youngest patients who were between 17 and 21 years of age. Nerve lesions accompanied by fractures showed poorer results, which the author attributed to delay in suturing the nerve, necessitated by the time required for healing of the fracture and also by complicating lesions of the soft tissues, so that it was often impossible to isolate the nerve from the bony callus. Lesions to the main arterial trunk of the affected extremity did not seem to alter the rate and degree of motor recovery. The influence of postoperative wound infections on motor recovery was not as great in secondary suture as in primary suture. Salvarsan was used locally in a small number of cases which could not be evaluated.

No difference in the quality of motor recovery could be observed following sutures performed with and without tension, and no harm was noticed following moderate stretching of the nerve segments.

The two-stage operation yielded good results in several cases in which it was impossible to approximate the nerve ends at the first operation. Recovery did not seem to be influenced by a rotation of the two severed nerve segments but was definitely poorer when a large loss of nerve substance was present. The author warned against a resection of the two nerve stumps where what was absolutely necessary. He also suggested an oblique resection of the two nerve ends when there was a difference in the diameter of the central and the distal stump in order to facilitate approximation and suture. He found that an immobilization period of 4 weeks was usually sufficient and that it had little to do with a secondary rupture of the suture line.

Although no specific effects of the postoperative treatment on recovery were noticed all patients received postural treatment, heat, galvanic and faradic stimulation, passive and active movements, general gymnastics, and especially rehabilitating activity. The qualitative results seemed to depend on the degree of motility preserved in the joints of the affected limb and on the absence of contractures. The main objective of the postoperative treatment was to preserve the full range of passive motility of the paralyzed extremity. It was clinically impossible to prove that the electrical treatments had any influence on recovery but they were considered justifiable because of their psychological effect.

Paine, Tom F.; Murray, Roderick; Harris, H. W. II; Ham, Finland; Maxwell, and Wilcox, Clere: Streptomycin in the Treatment of Certain Gram Negative Bacillus Infections of the Central Nervous System. *Am. J. M. Sc.*, 1947 213 676

The report presented deals with 5 cases of gram negative bacillus infections of the meninges in which recovery followed treatment with streptomycin. The causative organisms were *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*) and *Hemophilus influenzae*, each in 2 cases, and *Bacillus proteus* in 1 case. In the past these organisms have been highly resistant to the action of both the sulfa compounds and penicillin.

The case reports are accompanied by charts showing the important findings in each particular case. The total daily intramuscular dose ranged from 0.2 gm. to 4 gm. The intrathecal dose consisted of 0.05 gm. in 1 ml. of sterile normal saline.

The authors evaluate the role of streptomycin in the cases of *Pseudomonas aeruginosa* meningitis. In case 1 the clinical and bacteriologic response of the patient following the institution of therapy was prompt. In this patient, the infection followed lumbar puncture and streptomycin was started relatively early in the course of the disease but only after several days of apparently ineffective penicillin and sulfadiazine therapy. In case 2 strepto-

mycin therapy was not begun until the seventh day of the disease, after 4 days of ineffective penicillin therapy. The response of the infant to streptomycin was only gradual and there was evidence of residual damage to the central nervous system after treatment. In the period of 7 days before streptomycin was begun there was more than ample time for *Pseudomonas aeruginosa* to have inflicted severe damage on the central nervous system.

In case 3 with *Bacillus proteus morganii* meningitis organisms disappeared from the cerebrospinal fluid only after the institution of streptomycin therapy, though some clinical improvement had occurred during the preceding period while penicillin and sulfadiazine were being given. Here again the recovery may be ascribed to streptomycin.

In case 4, with *Hemophilus influenzae* meningitis streptomycin therapy was attended by a prompt clinical and bacteriologic response. Since no other medications were used in this patient, streptomycin would seem responsible for the cure obtained in this infant. An elevation of temperature and a pleocytosis of the cerebrospinal fluid was noted in 3 of the patients following the intrathecal injection of streptomycin.

The transient untoward effects of the local use of streptomycin would indicate that the intraventricular and intrathecal routes for the administration of streptomycin should be used with caution. Streptomycin administered by the intrathecal and intramuscular routes would seem to be the drug of choice in the treatment of meningitis due to these gram negative bacilli. HOWARD H. LANDER, M.D.

Craig, Winchell McK. and Abbott, Kenneth H.: Surgical Considerations in the Treatment of Hypertension. *Ann. Surg.* 1947 135 608.

The surgical treatment for the relief of hypertension has passed through the stage of radical rhizotomy into that of extraspinal resection of the splanchnic nerves and the thoracic and lumbar sympathetic ganglia and trunks.

Classification and grouping of the disease have been chosen arbitrarily for a comparison between the medical treatment, on the one hand and various types of surgical procedures, on the other. No satisfactory single criterion for the prediction of successful operations has been developed. It has been agreed that even the most extensive of the operations cannot change the clinical status of hypertension which has advanced to the degree of irreversible changes in the vessels of the heart, kidneys, brain, and other organs.

The nature of the operation is physiologic rather than pathologic and the results depend on the physiologic response of the vascular system. All types of sympathectomy and splanchnicectomy have been followed by arrest of the progress of the disease and alleviation of symptoms. Although it is true that the more extensive operations have resulted in greater denervation of the vascular system they also result in a more extensive cutaneous area of non-

of distinct value when gaps occur after the open type of injury. Neither type of injury should be denied the benefit of surgical treatment when with persistent physical therapy the progress of recovery has reached a stand still. Neurolysis with careful removal of all constricting bands and scar tissue should be followed by a regimen of physical therapy planned for many months. Estimations of the recovery of function in all peripheral nerve surgery must be based upon the recovery of sensation in isolated areas of supply and upon the recovery of movement in muscles whose action cannot be imitated by supplementary movements.

Craig, Winchell McK. and Abbott, Kenneth H.: Surgical Considerations in the Treatment of Hypertension. *Ann. Surg.* 1947 125 663.

The surgical treatment for the relief of hypertension has passed through the stage of radical rhizotomy into that of extraspinal resection of the splanchnic nerves and the thoracic and lumbar sympathetic ganglia and trunks.

Classification and grouping of the disease have been chosen arbitrarily for a comparison between medical treatment, on the one hand and various types of surgical procedures, on the other. A satisfactory single criterion for the prediction of successful operations has been developed. It has been agreed that even the most extensive of the operations cannot change the clinical status of hypertension which has advanced to the degree of irreversible changes in the vessels of the heart, kidneys, brain and other organs.

The nature of the operation is physiologic rather than pathologic and the results depend on the physiologic response of the vascular system. All types of sympathectomy and splanchnicectomy have been followed by arrest of the progress of the disease and alleviation of symptoms. Although it is true that the more extensive operations have resulted in greater denervation of the vascular system they also result in a more extensive cutaneous area of noc-

sweating which produces discomfort to the patient in adjusting himself to climatic changes, and further discomfort because of excessive sweating in the unaffected areas.

Newell, John L. and Smithwick, Reginald, H.: Pregnancy following Lumbodorsal Splanchnicectomy for Essential and Malignant Hypertension and Hypertension Associated with Chronic Pyelonephritis. *N. England J. M.*, 1947 836 851

Pre-existing hypertension with or without renal disease makes for a poor prognosis in pregnancy both for the mother and the child. Pregnancy is considered to accelerate the progress of these diseases. Severe hypertension is considered by many to be an indication for therapeutic abortion.

The present article is based on 14 cases of arterial hypertension with blood pressures averaging 196 systolic and 130 diastolic. Prior to splanchnicectomy the blood pressures of these patients were studied during the ensuing pregnancies and at 6 weeks post partum. In one case, the splanchnicectomy was performed during the first trimester. Following the splanchnicectomy the average blood pressures, prior to the pregnancies, averaged 135 systolic and 87 diastolic only 2 patients had persistent albuminuria.

The diagnosis of the hypertension was as follows: the condition in 7 patients was classified as essential hypertension, in 2 as essential hypertension and associated chronic pyelonephritis, 2 patients developed both hypertension and pyelonephritis during their first pregnancy; there were 3 cases of malignant hypertension with pyelonephritis in 2. In all the cases hypertension antedated the pregnancies under discussion and in 3 cases previous pregnancies were interrupted because of hypertension.

In 9 cases the blood pressure remained within normal limits during pregnancy without albuminuria. In the other 5 there was very little change in blood pressure until the third trimester. In one of these, a four plus albumin necessitated interruption of the pregnancy at the thirty-fourth week. There is a complete clinical record of each patient. It seemed to the authors that it would be most unlikely for the majority of these patients to have had living children without severe cardiovascular damage unless the splanchnicectomy had been performed. It appears that after a satisfactory response, a carefully supervised pregnancy is safe and permissible and arrangements may even be extended to include cases of malignant hypertension which would otherwise be extremely hazardous.

ANDREW VON BRUGGEREN M.D.

He believes that in the majority of cases the diagnosis of intraocular neoplasm offers no special difficulty but that certain tumors are difficult to differentiate from primary glaucoma idiopathic retinal detachment, choroidal detachment senile macular exudative retinitis, hydatid cyst, benign melanoma localized inflammatory conditions, and secondary tumors. He believes that in addition to a thorough history and complete examination of the eyes, certain points are of help in making the diagnosis. A detachment secondary to a tumor does not have a retinal hole pigmented cells in the anterior chamber may indicate an intraocular tumor. Among these cases the intraocular pressure was elevated in 50 per cent and low in 3 per cent. However, other series were not as consistent. The author thinks that the use of the scleral puncture, scleral flap and exploratory needle are unjustifiable.

Aids in diagnosis of the more difficult iris sarcoma were its limitation of the iris motility its preference for the lower quadrants, its greater tendency to rise above the iris level and its encroachment on the iris angle. Intraocular sarcomas are most common in the choroid less frequent in the ciliary body and rare in the iris. Bilateral sarcoma is extremely rare. In the choroid the tumor begins in the stroma, spreading between Bruch's membrane and the sclera. It then breaks through Bruch's membrane and expands rapidly into the vitreous forming the collar stud appearance with its central constriction. The tumor also tends to follow the perforating channels of the sclera into the orbit, and to metastasize by the blood stream.

The author uses the pathological grouping of spindle cell round cell, spindle and round cell epithelioid cell and mixed cell types. The spindle cell type was the most common and the epithelioid cell type was rare. The mixed cell tumors were made up of all these types of cells and were the most fatal. The choroidal sarcomas were extremely vascular and were occasionally ossified. The origin of the melanoblasts is still undecided but the author believes they are of both epiblastic and mesoblastic origin. He believes that the malignant melanoma is of mesodermal origin and therefore a true sarcoma.

The mortality rates showed that 27.9 per cent of the patients had died of sarcoma at the end of 3 years, 35.8 per cent in 5 years, and 55.5 per cent in 10 years. The author found that the patient was quite safe after 10 years. Intraorbital extension increased the mortality rates but involvement of the optic nerve or venous outlets did not. Patients under 30 years of age had a better prognosis. The author's findings tended to substantiate those of Callander and Wilder in that the patients with large amounts of reticulin throughout the tumor had a good prognosis.

The eye and the tissues immediately behind it should be removed as soon as the diagnosis has been made. In those cases of known extraocular spread, the statistics did not show any better results with exenteration than with radiation therapy. If the growth is in the patient's only eye or if the patient refuses to

have the eye removed the author suggests the implantation of radon seeds into the growth or an iridectomy in the case of an iris tumor.

ROBERT H. JOHNSON M.D.

Weekers, L.: Adhesive Episcleral Reaction in the Operative Treatment of Retinal Detachment. *Brit. J. Ophthalmol.*, 1946 30 715

The author emphasizes the desirability of producing an adhesive episcleral reaction as well as an adhesive chorioretinitis in the operation for the correction of retinal detachment.

An incision was made through all layers of the eyes of rabbits and of human beings prior to enucleation with a very thin small cataract knife. Subsequent histological examination revealed the episcleral tissue to have entered the scleral incision and to have formed a union with the retina, which prevented a postmortem detachment at the points of perforation although the retina was elsewhere detached. This was true even when the eye was enucleated as short a time as 3 or 4 days after the puncture. Healing of the sclera itself was found to be slight or negligible.

From these experiments the author concludes that the episcleral reaction should be striven for in cases of retinal detachment to assist in holding the retina in position. This can be accomplished only if the sclera is completely perforated. While this can be most readily accomplished by a cataract knife it involves some risk of hemorrhage. The author therefore uses an ordinary angled and insulated diathermy needle 2 mm. in length and 0.15 mm. in diameter and leaves the current on while inserting and removing the needle the entire procedure requiring less than a second for each puncture. There should be no loss of subretinal fluid. The author favors the use of the nonperforating diathermic electrode prior to the perforations to promote a wide area of adhesive chorioretinitis. Following the multiple diathermic punctures the subretinal fluid should be evacuated. For this the galvanocautery is preferred several short applications being made at the same spot and exploration with a lacrimal probe is done if necessary.

WILLIAM A. MANN M.D.

Levatin P.: Atrophy of the Optic Nerve following Hemorrhage. *Arch. Ophthalmol.*, Chic. 1947 37 18.

Amblyopia following an acute loss of blood occurs but rarely, an average of one case a year having been reported for the past 25 years. It seems probable that the pathogenesis of the condition lies in degeneration of the ganglion cells of the retina as a result of the ischemia, although there are numerous objections to this theory. In addition to the effect upon the ganglion cells there may be direct destruction of the optic nerve fibres in the region of the lamina cribrosa.

In the case reported by the author there was a massive hemorrhage from a duodenal ulcer in a 34 year old white man with reduction in hemoglobin to 25 per cent, with little improvement in the blood picture for 13 days, due to continued bleeding in spite

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Piccolo V and Golsis, M: *Histological Notes on Fibrocystic Mastopathy before and after Treatment with Male Sexual Hormone* (Rilevi istologici nella mastopatia fibrocistica prima e dopo trattamento con ormone sessuale maschile) *Tumori* Milano 1946 32 175

The efficacy of testosterone propionate in chronic mastitis, periodical painful breast and menstrual and menopausal disorders was first observed by Demarest and Capitan in 1937. The excellent results with sexual hormones obtained in a case of mastopathy with hyperfolliculinemia led the authors to try it in 17 more patients. In 16 of them the testosterone acetate caused the pain to leave and arrested the progress of the illness. In 1 case only the results were not satisfactory possibly because the patient was old and the mastopathy had been present for many years. Premenstrual monthly doses of from 30 to 90 mgm. were given for a few months. The results obtained by Demarest and Capitan were soon confirmed by others (Turpault, Loeser, Mighavacca, Borghetti,) so that today the use of male sexual hormones is almost specific in cases of fibrocystic mastopathy in the female.

Various authors who have interested themselves in this problem have reported a diminution or disappearance of the adenomatous and cystic nodules and cessation of pain. However no one has confirmed the results with histopathological studies.

This the authors have done and in this article they report the clinical and histopathological results in the mammary gland before and after treatment with testosterone propionate (perandren). A biopsy of the gland was taken before and after the treatment was started and the treatment consisted of 25 mgm per dose until a total of 125 mgm. was reached. After 2 months more tissue was removed for microscopic study. The tissue was removed for an area distant from the previous biopsy site to eliminate traumatic reactions. In some cases a third microscopic examination was made. Following a histopathological discussion of the biopsy specimens before and after the treatment with perandren the authors state that there was a reduction of the epithelial elements and of the cystic formations, and an increase of the connective tissue elements leading to compression and almost strangulation of the epithelial elements. These changes namely coarctation and individualization of the lobules, a tendency toward or complete disappearance of the cysts and reduction of the tubules of the Mantelgewebe are more marked in tissues removed 3 or 4 months after the treatment. Tissue removed from 1 to 2 months after the treatment shows intermediate changes. The ultimate conclusion is that testosterone propionate causes a gradual fibrosis and involution of the epithelial elements, an action which is antagonistic to the hyperplasia of the elements of the mammary gland. The authors acknowledge that some authors have obtained opposite results, namely a marked

Fig. 1. Before treatment. Hyperplastic cystic proliferation of medium grade

Fig. 2. One month after treatment. Beginning involution with reduction of the "Mantel Gewebe."

Fig. 3. Three and one-half months after treatment. Fibrosis of the Mantel Gewebe and marked involution of the glandular elements with dispersion. Typical involution.

increase of the epithelial elements and of the connective tissue, and they mention the anticarcinogenic action of the male hormones (as reported by Prudente and others) which is explained by endowing the male hormones with an action antagonistic to the estrogens.

The authors believe that continuous treatment with androgens may lead to masculinization of the female breast for the same reason that treatment with folliculin has caused gynecomastia in the male.

The dosage of the male hormone depends on the amount of folliculin present in the patient; therefore, some method of computing its amount in the blood should be established. Large doses of perandren are recommended in order that the fibrocystic breast may be kept under the favorable influence of this hormone.

JOSEPH M. A. PATE, M.D.

Mattina, M.: Considerations on the Late Results of Post-operative Roentgen Therapy of Cancer of the Breast. (Considerazioni sui recenti risultati a distanza della Roentgenterapia post-operatoria del carcinoma mammario). *Gior. med.*, Palermo, 1946, 3, 371.

The author compares the results obtained in a group of 33 patients with carcinoma of the breast subjected to postoperative roentgen therapy during the years 1938 and 1939, with the results in another group of patients (10) operated upon during 1943 and unable to undergo x-ray therapy because of the exigencies of the war. The results show a diminished mortality in the patients of the first group as well as fewer recurrences (26%) as compared to the recurrences in the second group (60%).

The conclusions of the author are as follows:

1. It is a necessary and indispensable part of the surgical cure to subject all patients with carcinoma of the breast beyond the first stage of Stenhal to postoperative irradiation soon after the healing of the incision. Delayed healing of the incision is not a contraindication to start irradiation.

2. Of the different techniques in vogue the one of Perussia is recommended. This consists of irradiation given in one series of from 2 to 3 weeks duration with administration in one area only of 2,500 to 3,000 roentgens at a focal distance of 60 cm.

3. The methods of Winta, Palmieri and Hoidfelder which require various series are to be used only when the technique of Perussia is contraindicated.

TRACHEA, LUNGS, AND PLEURA

Di Rienzo, S.: Bronchial Dynamics. Its Roentgenologic Manifestations (Dinamismo bronchiale. Sue manifestazioni radiologiche). *Bol. Inst. dia. quir.* B. Air 1946, 2, 45.

In addition to anatomic features bronchi also possess dynamic characteristics which may easily escape detection not only in a cadaver but also in vivo during the bronchoscopic examination. Such dynamic factors can be studied best after the introduction of an opaque medium into the bronchi.

Bronchial dynamics depend on 3 anatomic structures: muscular fibers, elastic fibers, and terminal nerve fibers. Smooth muscular fibers form functional radicular and alveolar sphincters.

The play of contractions in lobular bronchi is not continuous but rhythmic, corresponding to respiration. During roentgenoscopic examination the continuous progress of contractions of the large air passages can be differentiated from the rhythmic movements of the smaller branches. The opaque column which advances during inspiration recedes during expiration under normal conditions, while in presence of pathologic lesions the movements may be absent or reversed.

Not infrequently bronchoscopic and roentgenologic findings contradict each other. The author cites an observation in a patient in whom the bronchography furnished negative results but repeated x-ray examinations after the introduction of an opaque medium into the bronchi established the diagnosis of malignancy.

Typical findings may be elucidated in asthma because the normal inspiratory impulse is absent.

Functional sphincters are responsible not only for physiologic reduction of the size of the bronchi but also for pathologic constrictions.

The muscular fibers surrounding the bronchi are innervated by the extrachondral subchondral, and subepithelial plexus. The fibers of the first mentioned plexus derive from the sympathetic system, while the fibers of the other two plexus formations come from the pneumogastric system.

Various local and general factors may influence the tone of the bronchial sphincters.

Cessation of normal dynamics of the bronchi with the resulting retention of the opaque medium is most frequently observed in bronchial cancer.

Various changes of normal bronchial dynamics may suggest nonexisting anatomic lesions and the employment of wrong therapeutic measures and therefore a knowledge of the various alterations of the bronchial dynamics is essential for diagnosis and proper therapy.

JOSEPH E. NARAT, M.D.

Fojanini, Guiseppe: Multiple Successive Abscesses of the Lungs. Clinical Study (Ascessi multipli successivi del polmone. Contributo clinico) *Arch. Ital. Chir.*, 1947 34 3

Multiple abscesses of the lungs can be divided into two groups: simultaneous or synchronous and successive. Various stages of evolution may be found in the second group. Septic or pyemic processes of embolic nature may produce pluricentric suppurative lesions in both lungs. After the primary abscess has taken a normal course for some time, complications arise in the form of a rise of temperature, pain in the chest, vomiting and increased expectoration. Especially the last mentioned sign suggests a clinical search for multiple abscesses and a roentgenologic checkup.

The author reports 8 cases of successive pulmonary abscesses. One patient ultimately recovered; the condition of 3 improved; 2 patients were left with a bronchial fistula, and 2 succumbed to the condition. From 3 to 19 months elapsed between the appearance of the first and second abscesses. Some patients recovered under conservative treatment while others require surgical intervention.

It cannot be definitely stated whether successive pulmonary abscesses may be considered exclusively as intrapulmonary metastases of the primary abscess. Dissemination of infection may originate from an extrapulmonary focus. Bronchogenic, lymphatic, and hematogenous paths of spread of the infection must be considered. The infection may invade the lungs by contiguity from suppurating lymph glands. Usually secondary abscesses develop after the primary abscess has ceased to provoke vomiting; therefore spread of infection by aspiration of the infected masses cannot be of great importance.

In order not to overlook the development of a successive pulmonary abscess the author advocates periodic x-ray studies at 15 day intervals.

The prognosis is not as bad as is generally assumed. Some abscesses may regress spontaneously; others yield to medical treatment while some must be attacked surgically. If no improvement is recorded after from 4 to 6 weeks of conservative treatment surgical intervention is indicated.

JOSEPH E. NARAT, M.D.

Blizard, J. Dewey and Swenson, S. A., Jr: Bilateral Lobectomy for Bilateral Bronchiectasis. *Arch. Surg.* 1947 54 483

The authors record 4 cases of bilateral bronchiectasis in which cure was obtained by bilateral lobec-

tomy. In all patients the lower lobes of both lungs were removed and in 1 patient the middle lobe of the right lung was also excised. In all but case 2 the patients are entirely free from symptoms. In case 2 there is some residual cough and sputum because the middle lobe of the right lung and the lingua of the upper lobe of the left lung are bronchiectatic, and the disease remains because it was not recognized prior to and at operation.

Eight operations and 9 lobectomies were performed in the 4 cases—all by intralobar dissection and the individual ligation technique, with intratracheal cyclopropane anesthesia and frequent intratracheal aspirations. In 2 cases bronchopleural fistula with empyema developed in each case after the first stage of operation, and in both cases the fistula closed spontaneously after drainage of the empyema. There were no deaths in this small series.

Removal of two major lobes either total pneumonectomy or bilateral lobectomy reduces the amount of lung tissue available for respiratory function so drastically that the cardiorespiratory capacity must be critically evaluated before each operation. It is interesting that in 3 of 4 cases the resections did not cause reduction in vital capacity but, on the contrary, produced sizable increases. Apparently the bronchiectatic lobes were relatively functionless. This is understandable in cases in which the diseased lobes are small, contracted, atelectatic, functionless masses. After lobectomy the residual normal lobes become emphysematous and apparently develop some increase in respiratory capacity. To realize fully the benefits of this compensatory change 3 or more months should be allowed between stages of operation. Probably the principal factors responsible for increasing respiratory capacity are the elimination of infection and of coughing and their interference with respiratory efficiency. The reduction in cardiac and respiratory reserve which occurs with aging limits the use of bilateral lobectomy to children and young adults, a younger age limit than that for unilateral lobectomy.

In no other type of surgical case does a successful outcome depend so much on constant observation and vigilant attention to details of preoperative, operative, and postoperative care. These patients had the constant attention of special nurses trained to encourage coughing and alert to any interference with a free airway. A resident surgeon skilled in tracheobronchial aspiration was always immediately available. The hemoglobin and the red cells were maintained at normal levels by the liberal use of blood transfusions before, during and after operation. The tracheobronchial tree was kept free of sputum as completely as possible by postural drainage before operation and by frequent tracheobronchial aspirations during and after operation. Chemotherapy was utilized prior to and after operation, first, with the sulfonamide drugs and later with penicillin, when it became available. Oxygen was administered in a tent as long as the patient felt that it was beneficial.

A fortunate importance is the fact that all the patients are enjoying not only good health but nor the lives, which the cough previously denied them. The 2 boys have resumed schooling and the maiden was married. Four case histories are given in detail.

JOHN J. MATONEY M.D.

Wetters, Roger E.; Clagett, O. Theron; and McDonald, John R.: Amyloid Disease of the Lung Treated by Pneumonecctomy. *J. Thorac. Surg.* 1947 14: 505.

Amyloid disease, other than the commonly recognized typical form secondary to a chronic debilitating disease, is now being recognized as a clinical and pathologic entity. It may occur in a more or less generalized distribution or may be localized to a portion of an organ, particularly in the connective tissue elements and walls of the blood vessels of the involved structure.

Deposits of amyloid substance which form localized nodules, masses or infiltrations, although uncommon, may simulate other pathologic lesions and require surgical removal of either a portion of the organ or the entire organ.

The mechanism of elaboration of this abnormal intracellular material in localized masses is not known and no evidence exists thus far that resorption of the deposits occurs either spontaneously or under the influence of conservative therapeutic measures.

A case of localized amyloid disease involving the main bronchus, its branches, and the corresponding branches of the pulmonary vessels at the root of the right lung was reported in the original article. Pneumonecctomy was performed after thorough study in an attempt to establish the cause of the repeated attacks of hemoptysis.

Localized amyloid disease, particularly in the respiratory tract can be responsible for sufficient alteration in the anatomy and physiology of the involved organ to be of clinical importance. In this case the clinical picture was essentially that of an interstitial, longstanding, low grade obstructing lesion of a major bronchus or its branches at times associated with brief episodes of hemoptysis and with a gradual decline of the presence of a debilitating pulmonary disease. That the process did not produce or persist as bronchostenosis was indicated by the absence of a significant degree of pulmonary suppurative distally. The history of the patient indicated that some impairment of function and drainage of the middle and lower lobes of the right lung had been present for

bronchial branch. Furthermore, the loss of the cilia of the surface epithelium overlying the amyloid process in the main bronchus and its branches suggested that a physiologic obstruction to the normal flow of bronchial secretion was present. There was no evidence of bronchial ulceration when the lung was examined in the laboratory. The source of the bleeding which resulted in the symptoms or produced the clot in the bronchial branch to the lower lobe, noted by the bronchoscopist was best explained on the basis of extravasation from small or medium sized bronchial blood vessels, the walls of which had been largely replaced and weakened by the amyloid deposits.

The roentgenograms did not suggest hilar infiltration in this case. This is especially remarkable in view of the fact that some degree of calcification was present in the mass.

Deposits of amyloid substance in tissues frequently are described in the literature as being grayish translucent masses which yield a characteristic color reaction when iodine is applied to their cut surfaces. In this case the gross picture did not show this classical picture and did not suggest a typical form of such lesions. The extremely tough, leathery consistency of the mass, as noted by both the surgeon and the pathologist, was of much more significance in the recognition of the nature of the process.

The staining characteristics of the amyloid substance are of considerable aid to the surgical pathologist in establishing prompt positive identification.

Moody James D. Trent, Josiah C., and Newton, George W.: An Endobronchial Balloon for the Control of Bronchial Secretions during Lobectomy and Pneumonecctomy. *J. Thorac. Surg.* 1947 14: 558.

A double-lumen balloon suction catheter for the control of bronchial secretions during lobectomy and pneumonecctomy is described. Its successful use in 22 lobectomies and 5 pneumonecctomies in dogs demonstrates that (1) no harmful effects are produced, (2) complete occlusion of the bronchus is obtained, (3) dislodgment during operation is very unlikely, (4) a wide margin of safety is present, and (5) there is little interference with anesthesia.

Clinical trials are now under way and will be reported later. It should be understood that this instrument has been designed for use only in pneumonecctomies or lower lobectomies and not in upper lobectomies. Experimental studies are now being carried out on a similar instrument constructed primarily for use in upper lobe resections.

authors. She has had pains in the left side of the chest for 18 years. On quite numerous occasions dyspnea on exertion appeared. From time to time the patient vomited and the expelled liquid contained echinococcus cysts.

An operation was performed under general anesthesia. The postoperative period was complicated by a pulmonary complication involving the right lung. Cysts were found in the sputum. A shadow presumably caused by a cyst was found in x ray pictures of the right lung before and after the operation.

Echinococcus invasion of the pericardium may be recognizable microscopically in some instances, while in others only a histologic examination will lead to the correct diagnosis.

In numerous cases reported in the literature the invasion of the heart and pericardium was combined with similar conditions in the viscera but in the author's case only a concomitant lesion of the lungs was found. In many instances numerous adhesions in the pericardium are caused by the invasion of echinococci. As a rule it is not necessary to drain the pericardial sac through the pleural cavity.

JOSEPH K. NARAT M.D.

Amargós, A.; Ugón V Armand; Langhero, P. and Di Bello R.: Three Cases of Cardiopericardiac Echinococcosis Treated Surgically (Tres casos de echinococcosis cardiopericardíaca operados) *Bol Soc. cir. Uruguay* 1946 17 504.

Two hundred cases of echinococcus disease of the heart and pericardium have been collected by the authors from the literature. Six of the patients were operated on.

The differential diagnosis must consider osteosarcoma of the ribs and aneurysm of one of the intercostal arteries if an intercostal tumefaction is present.

The authors report 3 cases of echinococcus invasion of the heart and pericardium. In all 3 a characteristic, deep inversion of the T wave in the electrocardiogram was found. Similar alterations of the tracings were found by other writers. The authors express the opinion that such changes in electrocardiograms alone or in combination with other clinical and laboratory findings are of great diagnostic value.

The 3 patients operated on by the authors offered anatomopathologic findings corresponding to various stages of evolution of the condition localized primarily in the myocardium and spreading gradually to the pericardium. In the first case an exudative fibrinopurulent pericarditis with a fibroplastic reaction of the parietal pericardium was found. In the second case a similar process was combined with the presence of floating intact vesicles. Roentgenographic studies revealed circular shadows caused by the presence of secondary vesicular echinococcus formations. This form corresponds to a rupture of hydatidiform cyst of the liver while the first type may be compared with a chronic hydatidiform choleperitonitis with a small amount of exudate in which residues of membranes but no intact vesicles float. In the third case multiseptate secondary echinococcus le-

sions were found. This type may be compared with similar specific supramesocolic and subhepatic conditions in the abdomen. While in the second case the evolution took 4 months it was of not less than 8 years' duration in the third case.

The first 2 patients recovered from the operation while the third succumbed to a secondary infection 30 days after the operation. In the first patient the lesion produced a pulsating intercostal tumefaction with cystic expansion.

In the first type in which no fertile hydatidiform formations are present, simple evacuation is indicated. In the second type with intact cysts and effusion an incision and evacuation of the cysts should be performed while in the third type without effusion but with secondary multivesicular cysts, a complete evacuation of the formations and an injection of formalin are suggested. In the first type a drain is not necessary or if one is inserted it should be removed not later than from 24 to 48 hours after the operation.

JOSEPH K. NARAT M.D.

ESOPHAGUS AND MEDIASTINUM

Garlock, John H.: Technical Problems in the Surgical Treatment of Carcinoma of the Esophagus and Upper Stomach. *J Thorac Surg* 1947 16 315.

Based on the experience with more than 200 cases, the author summarizes some of the advances in technique and over all management of surgery for carcinoma of the esophagus and upper part of the stomach. They may be enumerated as (1) careful preoperative preparation (2) expertly administered anesthesia, (3) atraumatic surgery with minimal loss of blood, free exposure and accurate suture methods, and (4) careful attention to many details of postoperative care.

The preoperative preparation aims at adequate correction of dehydration, avitaminosis and disturbances of the protein metabolism and mineral components.

Fig. 1 (Garlock) Mobilization of the lower esophagus and stomach. Lesion is located at the cardia.

Its removal ordinarily is a simple procedure, but may be rendered difficult as a result of perforation into a bronchus, inflammatory fusion with the hilar structures or pericardium or malignant extension.

The neurofibroma, being a solid tumor and located in the posterior mediastinum, is subjected to unequal pressure from the vertebrae and ribs on one side and the yielding mediastinal tissue and pleura on the other. Hence this type of tumor becomes flattened on one side to conform to the surface of the costo-vertebral gutter in which it usually lies. This solid slowly growing tumor may spread the ribs or produce erosion as a result of long continued pressure. The removal of a small neurofibroma is neither difficult nor dangerous. The long neglected tumor, however, may cause paralysis or irreversible structural deformity, the condition becoming incurable.

The congenital cyst may be discovered at any age. The symptoms may be very vague, and the diagnosis may be made on x-ray examination or at autopsy. Suggestive symptoms are substernal pressure, cough, swelling of the neck, and pain in the left chest and arm. Dyspnea and pleurisy may occur. Cough productive of blood, pus and hair may occur. Physical signs are usually absent, although dullness over the site of the tumor may occur.

With neurofibromas, backache, mediastinal pressure, pain, deformity of the thorax, exertional dyspnea, and evidence of obliteration of the subclavian artery may occur.

Since a diagnosis can rarely be made from the clinical findings alone, adequate x-ray examination should be made early. It is important to include fluoroscopy with barium visualization of the esophagus,

posteroanterior stereoscopic films of the chest, a lateral film, and a film to record bony detail.

The dermoid cyst and the teratoma usually lie in the anterior mediastinum, while the bronchial cyst and the neurofibroma are located in the middle or the posterior mediastinum. All may project into either the right or left pleural cavity. The dermoid cyst and the teratoma vary in size from 1 cm. to 20 cm. in diameter. They are single, well circumscribed tumors. They often show calcification in the walls, and portions of teeth and irregular bone spicules within the tumor. Differentiation must be made from echinococcus cysts, which may show intramural calcification, but no teeth or bone.

Six cases are reported: 1 dermoid cyst, 1 teratoma, 1 bronchial cyst, 1 ganglioneuroma, and 2 neurofibromas. The operation in each case was done under gas-oxygen-ether intratracheal anesthesia. A posterolateral, anterolateral or midsternal thoracotomy incision was used, according to the location of the tumor and the probability of the best exposure in each case. After operation the thoracic wound was closed tightly about an intercostal catheter placed into the pleural cavity for drainage, following re-expansion of the lung. The catheter was kept on suction drainage (13 cm. negative pressure measured in water) until serous pleural effusion ceased, about the third or fourth postoperative day. Fine silk was used for the ligature and suture material.

Since the tumors are potentially dangerous, their early discovery through annual chest roentgenography of the population is recommended, and their early operative removal is urged.

SAMUEL KAHN, M.D.

Fig. (Garlock) Diagrammatic representation of the completed operation of total gastrectomy performed through a combined abdominothoracic incision and showing the Y-anastomosis of the jejunum. About 3 inches beyond the duodenojejunal junction the jejunum and its mesentery has been divided. The distal end is brought through an opening in the mesocolon and sewed to the opened end of the esophageal stump in the usual manner. The proximal end of jejunum is implanted end-to-side into the distal portion below the mesocolon.

Anesthesia includes routine tracheal intubation and careful removal of tracheobronchial secretions.

The problems in surgical technique vary to some extent with the location of the carcinoma.

In midthoracic carcinoma, preservation of an intact blood supply to the mobilized stomach is obviously important. The upper esophageal stump likewise poses a similar problem because of its probable meager blood supply and advice against excessive mobilization of its upper segment is sound. The left gastric artery can be sacrificed safely. Further mobilization of the stomach can be secured by dividing the gastroepiploic omentum if the gastroepiploic vascular arch along its greater curvature is preserved.

Exposure is secured by an incision in the sixth intercostal space with division of the fourth, fifth, sixth, seventh, and eighth ribs near the spine. The phrenic nerve is routinely crushed. The anastomosis between the stomach and esophagus is made in two layers with interrupted nonabsorbable sutures, the stomach being telescoped over the suture lines. The stomach is suspended from the chest wall and the diaphragm is carefully closed around the stomach. Two instances of herniation are mentioned.

In carcinoma of the lower one-third of the esophagus and cardia of the stomach, the specimen obtained by esophagoscopy biopsy is credited with defining the origin of the carcinoma, squamous cell tumors arising in the esophagus and adenocarcinomas being believed to represent primary gastric neoplasms.

The operative exposure is secured through a combined abdominothoracic incision. With the patient in lateral position an upper left rectus incision is made and operability through it is determined. If suitable, the incision is extended upward and then outward in the eighth intercostal space to the vertebral border of the scapula or beyond. The chest is opened and the diaphragm incised radially from the esophageal hiatus. This approach permits accurate handling of the esophagus from the aortic arch down and of all of the stomach, as well as of the spleen and tail of the pancreas, if necessary. The wound is closed in layers, with pericostal sutures, and the pleural cavity is drained by catheter.

In total or extensive gastric resections, an esophagojejunostomy has proved very satisfactory especially the "Y" anastomosis of Roxx. A jejunostomy for early feeding is used being made prior to abdominal closure.

Postoperatively an oxygen tent adequate sedation, parenteral penicillin and care exercised to insure complete pulmonary re-expansion are essential.

Jejunostomy feedings may be started promptly but oral feedings are begun on the fourth day. Transfusions are used as indicated.

HIRSH T. LANGSTON, M.D.

Silveus, Esther and Adams, Ralph: Benign Mediastinal Tumors: A Report of 6 Cases with Analysis of Diagnostic Criteria and Advocacy of Surgical Removal. *Surg. Clin. N. America*, 1947, 37, 306.

Mediastinal tumors are not rare and are believed in many instances to be congenital anomalies such as dermoid cysts, teratomas, and bronchial cysts. The most common mediastinal growth is the neurofibroma. The congenital tumors and the neurofibroma (and ganglioneuroma) exhibit several similar clinical features. They are round or ovoid in shape. They originate in the mediastinum, close to the midline. As they grow larger, they extend laterally against the lung, or anteriorly or posteriorly against the heart and thoracic wall with associated pressure phenomena. There are, however, differences of behavior between the cystic and solid tumors.

The cyst is round on fluoroscopy. It may show a slight change in configuration with change in the patient's position. The rate of growth of the benign cyst is slow and erosion of the surrounding structures does not occur. Such a cyst occasionally enlarges very rapidly because of accumulation of fluid within infection or malignant degeneration and it is for these reasons that it is potentially dangerous.

Its removal ordinarily is a simple procedure but may be rendered difficult as a result of perforation into a bronchus, inflammatory fusion with the hilar structures or pericardium or malignant extension.

The neurofibroma being a solid tumor and located in the posterior mediastinum is subjected to unequal pressure from the vertebrae and ribs on one side and the yielding mediastinal tissue and pleura on the other. Hence this type of tumor becomes flattened on one side to conform to the surface of the costo-vertebral gutter in which it usually lies. This solid slowly growing tumor may spread the ribs or produce erosion as a result of long continued pressure. The removal of a small neurofibroma is neither difficult nor dangerous. The long neglected tumor however may cause paralysis or irreversible structural deformity the condition becoming incurable.

The congenital cyst may be discovered at any age. The symptoms may be very vague and the diagnosis may be made on x ray examination or at autopsy. Suggestive symptoms are substernal pressure, cough, swelling of the neck and pain in the left chest and arm. Dyspnea and pleurisy may occur. Cough productive of blood, pus and hair may occur. Physical signs are usually absent although dullness over the site of the tumor may occur.

With neurofibromas, headache, mediastinal pressure, pain, deformity of the thorax, exertional dyspnea, and evidence of obliteration of the subclavian artery may occur.

Since a diagnosis can rarely be made from the clinical findings alone, adequate x ray examination should be made early. It is important to include fluoroscopy with barium visualization of the esophagus.

posteroanterior stereoscopic films of the chest, a lateral film and a film to record bony detail.

The dermoid cyst and the teratoma usually lie in the anterior mediastinum while the bronchial cyst and the neurofibroma are located in the middle or the posterior mediastinum. All may project into either the right or left pleural cavity. The dermoid cyst and the teratoma vary in size from 1 cm. to 30 cm. in diameter. They are single well circumscribed tumors. They often show calcification in the walls and portions of teeth and irregular bone spicules within the tumor. Differentiation must be made from echinococcus cysts, which may show intramural calcification but no teeth or bone.

Six cases are reported: 1 dermoid cyst, 1 teratoma, 1 bronchial cyst, 1 ganglioneuroma and 2 neurofibromas. The operation in each case was done under gas oxygen-ether intratracheal anesthesia. A posterolateral, anterolateral or midsternal thoracotomy incision was used according to the location of the tumor and the probability of the best exposure in each case. After operation the thoracic wound was closed tightly about an intercostal catheter placed into the pleural cavity for drainage following re-expansion of the lung. The catheter was kept on suction drainage (15 cm. negative pressure measured in water) until serous pleural effusion ceased about the third or fourth postoperative day. Fine silk was used for the ligature and suture material.

Since the tumors are potentially dangerous, their early discovery through annual chest roentgenography of the population is recommended and their early operative removal is urged.

SAMUEL KAHN, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Harper, Fred R.: Thoracoabdominal Approach to Upper Portion of Abdomen and Upper Pole of Kidney *Arch. Surg.* 1947 54 517

In this article the technical feasibility of traversing the diaphragm is discussed and a surgical technique is presented. With the aid of illustrative cases it is shown how such an approach gives a better understanding of some of the lesions encountered in the region of the diaphragm.

The patient is placed on the operating table in a true lateral position with the left side up. Endotracheal anesthesia induced with a nitrous oxide-oxygen-ether mixture is used. The incision is made over the ninth rib and extended from the angle of the rib to the anterior margin of the costal arch. The ninth rib together with its costal cartilage is removed subperiosteally and the thorax is opened through the periosteal bed. The thoracic cavity is then explored and any adhesions to the diaphragmatic pleura are divided. It is well at this time to divide the pulmonary ligament and crush the phrenic nerve. The costal arch is then divided and the edge of the diaphragm picked up to start the incision through this structure. It is split from its costal edge to the esophageal hiatus. Rib spreaders are then inserted which open the incision sufficiently to give adequate exposure to the structures from the pylorus of the stomach to the arch of the aorta. It is necessary to

Fig 2. Drawing illustrating transdiaphragmatic retroperitoneal approach to the adrenal gland and the upper pole of the kidney

divide the peritoneal reflection from the cardia of the stomach and the lower end of the esophagus. At the completion of the operation the diaphragm is closed with two rows of interrupted cotton or silk sutures, and the thoracic incision is closed in the usual manner with interrupted cotton sutures. In most cases it is not necessary to use suction drainage but in cases in which an anastomosis has been made between the stomach and the esophagus it is advisable. An oxygen tent is used routinely for 24 to 48 hours after operation. After that the patients are allowed to get out of bed.

Carcinoma of the cardiac end of the stomach and the lower portion of the esophagus requires good exposure for adequate resection of both organs. With the incision just described the resection and anastomosis of the organs can be made with ease under direct vision. Bleeding is easily controlled and the split diaphragm can be sutured to the stomach at the desired level.

Esophagogastrectomy has two very distinct advantages over total gastrectomy and esophagojejunostomy in that the resection is more complete and the operation is more physiologic as two thirds of the stomach can be saved.

Fig. (Harper). Drawing illustrating the exposure obtained from the thoracoabdominal approach

SURGERY OF THE ABDOMEN

The thoracoabdominal approach is ideal for the exploration and repair of large hiatal diaphragmatic hernias. The abdominal approach to these hernias is more difficult and less advantageous. The same can be said for diaphragmatic hernias that are associated with peptic ulcer or achalasia of the esophagus.

The transdiaphragmatic approach is also the ideal one for retroperitoneal organs lying below the diaphragm such as the adrenal gland and the upper pole of the kidney. In a case of a tumor of the adrenal gland this approach was found to be simple and it eliminated considerable manipulation of the tumor with the possible consequent danger of a rapid rise in blood pressure as a direct result of such manipulation.

In the discussion, GALT stated that one must not overlook the added difficulties and possibilities of complications in this combined operation. When the thorax is opened respiration must be kept under control in order to have a clear view of the operative field. This demands a well trained anesthetist. Also there is the problem of re-expanding the lung and obliterating the dead space as rapidly as possible to forestall infection, atelectasis and pleural effusion. With the proper personnel this approach has advantages far greater than the abdominal approach. The casual operator however finds it extremely difficult to expose this area. The site of incision will vary according to the habitus of the patient. In the pyknic patient it will probably have to be placed higher whereas in the asthenic type it may be 1 or 2 ribs lower.

ROBERT TOWN, M.D.

Dorjoo A. Dermoid Cyst of the Mesentery (Sulle cisti dermoidi del mesentere) *Ann. Ital. chir.* 1947 24 82

The author describes a case of dermoid cyst of the mesentery. Up to the present time only 50 cases have been recognized. Stressing the diagnostic difficulties he affirms the possibility of an exact diagnosis by means of an accurate clinical examination and roentgenological findings.

A 38 year old male patient entered the hospital following a diagnosis of cholecystitis. He complained of cramplike pain of the epigastrium which radiated to the umbilical region on the right and toward the back. The pain was not influenced by food or by change in position. After a few days on a diet the condition improved and the patient was discharged. Only to have two similar attacks in a short period of time. When he again entered the hospital a tumor like mass was found about the size of a large orange, smooth and of hard rubber consistency. It was extremely tender however no fluctuation could be elicited. When the mass could not be felt unrelaxed patient roentgenogram revealed an opaque shadow in the right upper quadrant while a barium A flat plate roentgenogram of cystic tumor of the mesentery showed a shadow.

With a preoperative diagnosis of cystic tumor of the mesentery pressing on the colon the patient un-

derwent surgery. The tumor was found to be the size of a full term fetal head of yellow color with a bluish tint. Minute blood vessels were on its smooth surface. The cut section gave the appearance of yellow sebaceous material with hair in a few places. There was a fibrotic sac from 1 to 3 cm in thickness and lined by a smooth mucouslike membrane. Microscopic examination revealed connective tissue with zones of stratified epithelium resembling epidermis hair follicles degenerated epithelium with cholesterol crystals, some hair rarely erythrocytes, and fat.

ARTHUR F. CROSSLAND, M.D.

The patient made an uneventful recovery.

GASTROINTESTINAL TRACT

Tomenius, John Hilding: A Study on the Gastric Sediment. *Acta med. scand.*, 1947 128 Supp 189.

This thesis of nearly 200 pages reviews an attempt to determine whether the pathologic processes which produce alterations in the gastroscopic appearance and functions of the gastric mucosa are reflected in the cytological picture of the gastric sediment and the gastric juice.

The leucocytic infiltration of the gastric mucous membrane and its diagnostic significance is discussed. The literature on the cytology of gastric juice is conflicting largely because acid-digested non-diffident sediment was analyzed by earlier investigators.

The author found that an isotonic (1-3 per cent) solution of bicarbonate dripped into the stomach prevented acid digestion and preserved a more differentiable cytologic picture of the gastric juice. Contamination by salivary esophageal and duodenal secretions was prevented by the use of a special gastric tube.

The cellular elements of the gastric juice were stained by a modification of Giemsa's technique and the cytologic picture was correlated with the clinical picture. The acidity secretion rate, mucous content and the roentgen and gastroscopic findings.

The clinical material comprised 77 cases including normal individuals and patients with chronic gastritis, pernicious anemia, gastric ulcer, duodenal ulcer, gastric carcinoma, leukemia, and miscellaneous conditions.

The patients with chronic gastritis fell into two groups: (1) those with chronic gastritis and acid secretion and (2) those with chronic gastritis and an atrophic mucous membrane without acid secretion. In the latter group the microscopic picture of the sediment resembled that of normal individuals. In the former group the cytologic picture differed directly chiefly by increased cell density and by predominance of the leucocytes.

In the group with duodenal ulcer and duodenal ulcer plus gastric ulcer without gastritis the cytology was normal.

In the group with cancer of the corpus of the stomach there was a marked leucocytic picture but

in patients with cancer of the cardia there were no leucocytes.

The miscellaneous cases showed a sediment like that found in normal individuals

EDWARD W. GIBBS, M.D.

Levin, Erwin; Hamann, Anna; and Palmer, Walter Lincoln: The Effect of Radiation Therapy on the Nocturnal Gastric Secretion in Patients with Duodenal Ulcer *Gastroenterology* 1947 3 505.

A temporary depression of gastric secretory activity in both humans and dogs resulting from the application to the stomach of roentgen rays in sufficient quantity has been shown by many workers. Palmer and Templeton were able to produce a complete achlorhydria to histamine, lasting from a few days to 9 months, in 35 of the 83 cases studied. In the present article the authors report the effect of radiation therapy on the nocturnal secretion in patients with duodenal ulcer.

Twenty-eight patients suffering from radiologically demonstrable, active, uncomplicated, duodenal ulcer were selected for the study. Prior to x-ray therapy all patients were placed on the usual hourly milk-cream and antacid regimen. At 9:00 p.m. nightly the stomach was completely emptied and a Levine tube was introduced through the nose, through which continuous Wangenstein suction was maintained for the ensuing 12 hours. Usually sleep was not disturbed. No antispasmodics or secretory depressants, such as atropine, were given. Three continuous nightly aspirations were obtained before x-ray treatment was started, and the free acidity was determined by the usual methods. Nocturnal secretion was studied in 9 patients during x-ray therapy and in 15 patients from 14 to 150 days after the completion of therapy.

Treatment consisted of the daily application of 1,350 to 1,710 roentgens to the body and fundus of the stomach through two portals located anteriorly and posteriorly and was carried out for a period of 10 to 14 days.

The fasting nocturnal gastric secretion of all patients was found to vary from 550 c.c. to 1,750 c.c., the average being 1,110 c.c. with a free acidity ranging from 18 to 122 clinical units, the average being 63. These findings are quite comparable to those of Dragstedt who studied the nightly gastric secretion by a similar method.

Of the 9 patients studied during the first week of ray therapy 7 showed a decrease and 2 an increase in the volume and free acidity of the night secretion. Of the 15 patients studied at varying intervals after therapy, 14 showed an average decrease of 47.4 per cent in volume. In 1 patient the total nightly volume was increased over that prior to therapy but the free acidity had disappeared. X-ray studies of this patient showed a considerable amount of obstruction which might have caused the increased volume. All patients showed a marked reduction of free acidity in the nightly secretion

which, in 13 of the 15 amounted to complete achidty. The duration of the depression of gastric secretory activity as manifested by measurements of the fasting volume and the gastric response to histamine is not intended as a part of the present study yet it is shown to be of regular occurrence for varying periods up to 5 months at the minimum.

WALTER CAMERON, M.D.

Brun, G., and Landellus, E.: Radical Resection for Chronic Ulcer (La résection radicale dans la maladie ulcéreuse chronique.) *J. Internat. chir. Bruxelles*, 1947 7 1.

The authors review 1,070 cases of patients operated upon for peptic ulcer with a primary mortality of 3.5 per cent.

The sex incidence was in a ratio of 4 males to 1 female. Sixty per cent of the patients were between 30 and 40 years of age. Two-thirds of the patients had an ulcer history of 5 or more years duration, and in one-third of the patients symptoms had been present for more than 10 years. Sixty per cent of the patients had symptoms between the ages of 20 and 40 years, and 9 per cent before the age of 20 years. In recent years fewer gastric and more duodenal ulcers have been found. In three-fourths of the cases the ulcer was duodenal or juxtapyloric in location. The majority of the ulcers were within from 0.5 to 1.0 cm. of the pylorus. Malignant degeneration was found in 1.6 per cent of the entire group and in 5 per cent of the gastric lesions.

The authors prefer a gastric resection of the Billroth II type with a retrocolic Polya-Keichl anastomosis, and this was done in 758 of the cases. The preoperative management is reviewed and the operative technique described in great detail. The post-operative care is also discussed.

A review of 450 cases observed for more than 5 years after operation by clinical and x-ray study showed good results and no recurrence in 97 per cent. The majority of the patients in this group had been operated upon because of recurrent symptoms and unsatisfactory progress on medical management.

The authors conclude that radical resection at an early stage in a young individual relieves the patient of subjective complaints, removes the risk of operation in an advanced stage, and eliminates the necessity for long continued dietary management.

EDWARD W. GIBBS, M.D.

Marshall, Samuel F. and Welch, Mark L.: Carcinoma of the Stomach. The Rat of Operability *Surg. Clin. N. America*, 1947 37: 63.

Between 1936 and 1945 in the Lahey Clinic 653 patients were operated on for carcinoma of the stomach. Resection was possible in only 169 patients, or 41 per cent of this group. Operability however was even much less (24.1 per cent) when one considers the number of resections possible in the cases in which the diagnosis of cancer was incontrovertibly established by various diagnostic methods. Of a group of 469 patients with a preoperative diagnosis

SURGERY OF THE ABDOMEN

of carcinoma only 113 had resection of their neoplasms.

The resection rate has declined slightly over this 10 year period. This is distinct evidence that no improvement in earlier diagnosis has been made. If an increase in the operability and the postoperative survival rate is to occur, earlier diagnosis of this type of malignancy must be made. This can probably best be done by means of x ray studies of all patients in whom gastric symptoms are present, regardless of age. Clinical interpretation of any type of gastric distress should not be condoned until adequate study has been made to rule out gastric malignancy. Only then is the physician justified in medical treatment of so-called indigestion. **SAMUEL KAHN, M.D.**

Marshall Samuel F. and Brown Lowell H.: Total Gastrectomy. Surg. Clin. N. America, 1947, 27, 621.

Total gastrectomy is a radical operative procedure designed to remove the entire stomach in that or instances for extensive malignancy arising in that organ. In the main there is only one definite indication for total gastrectomy—the presence of a tumor which so involves the stomach that it cannot be removed by partial gastrectomy. Total gastrectomy is to be avoided if all demonstrable tumor cannot be removed at the time of operation. Also evidence of widespread or distant metastases precludes the employment of this operation. Should there be involvement of the adjacent organs, the operation is advisable only if the involved areas can be included in radical extirpation of the malignant lesion and this is seldom possible. Portions of the pancreas should be removed in this majority of these cases. This does not increase the mortality rate and simplifies the complete mobilization of the stomach.

Total gastrectomy is indicated in tumors of the cardia and fundus, or in widespread malignant disease confined to the stomach such as linitis plastica.

When x ray studies indicate extensive involvement of the stomach which is involved. Usually gastrectomy must be considered it is important to determine whether the esophagus will be found free of encroachment on the esophagus is evidence of this. Should the x rays and esophagoscopy indicate involvement of the esophagus, transhiatic resection of the cardia, or even total gastrectomy should be done by this route.

In all of the group of 95 cases reported resection was done by the transabdominal route. This operation carries less operative risk and a more thorough removal of the lymphatic glands can be done through the abdomen. Continuous spinal anesthesia has been used in all cases and maintained for long periods with perfect relaxation and without shock. It can be supplemented by curare or sodium pentothal if greater relaxation is needed during the procedure. There were 27 postoperative deaths in this series of 95 cases. Fifteen deaths resulted from contamination and infection. Eight deaths followed serious chest complications. Although some of these complications could possibly have been avoided in the earlier cases by the use of chemotherapeutic agents, it is important to emphasize that clean surgery, lack of trauma and absence of contamination are the most important factors in preventing the complications. Cardiovascular complications caused 4 deaths. The operative mortality in 46 cases, during the period from 1927 to 1942 was 41.3 per cent. In 49 cases operated on since 1942 the operative mortality was 16.3 per cent.

Grette, Stent: A Contribution to the Knowledge of Primary True Concrements in the Small Bowel. Acta chir. scand., 1947, 95, 387.

The author has observed one case of true concretions of the small bowel. Ten similar cases have been reported previously in the literature and are discussed here. The case presented by the author is discussed in detail. The essential cause in the formation of enteroliths must be of a mechanical physical nature as the chemical conditions are practically always identical. Diverticula and bowel strictures play an important role in the creation of true bowel concretions. The retention of developing enteroliths and the stagnation of chyme favor the deposition of different chemical substances. Enteroliths of different chemical nature have been formed by principally the same process: the composition of the stone being the chemical nature of the surroundings. A low pH enhances the precipitation of choleic acid, such as is found in the upper ileum where there is an alkaline reaction. Calcium oxalate and zinc sulphide can precipitate either in an acid or alkaline medium.

True small bowel stones are of two types: (1) a solitary rounded larger stone obstructing a small bowel which has no other hindrance for passage, formed more likely, in diverticula, and at times if large enough causing symptoms when delivered into the free lumen of the bowel (most choleic acid stones have been of this type) or (2) one or more often small concretions found just above an incomplete constriction. Stones of mineral salts no doubt have been formed in front of the obstruction of the bowel immediately in front of the local dilatation. Enteroliths of other chemical composition can also have developed in diverticula higher up in the bowel and been stopped after having invaded the free gut in front of the stricture.

RICHARD J. BERNETT JR., M.D.
Acta chir. scand.

S. Krook, S.: Obstruction of the Small Intestine Due to Adhesions and Bands. Acta chir. scand., 1947, 95, Supp. 125.

The author deals with the problems of abdominal adhesions and intestinal obstruction in a most exhaustive manner. The first portion of this study is devoted to an extensive analysis of the literature pertaining to peritoneal adhesions, their etiology

pathogenesis, and research concerning their prevention. The statistical material comprises 477 cases of intestinal obstruction due to adhesions, taken from the records of 5 hospitals over a 20 year period.

From a review of the literature on the prevention of adhesions, the inevitable conclusion is reached that the only reliable means we have to date for the prevention of adhesions is to spare the peritoneum from infections and mechanical traumas. Attempts to prevent adhesions with so-called lubricants often have the opposite effect, and the results from experiments have been negative or doubtful. The intra-peritoneal use of heparin for this purpose is too dangerous for widespread application and is still of doubtful value.

A review of the literature indicates that the high mortality of intestinal obstruction at the beginning of the twentieth century has been lowered until it is now below 50 per cent. The duration of symptoms has a vital bearing on the result of the treatment, which, in itself, depends on many factors such as the age of the patient and whether or not there is strangulation. The mortality associated with every operation other than simple reduction of adhesions is high and is more dependent on the patient's condition than on the nature of the intervention. About 30 per cent of all cases of intestinal obstruction are complicated by strangulation. Despite many articles pointing out the diagnostic features of strangulation, it is nonetheless very difficult in many cases to distinguish strangulation obstruction from simple obstruction at a sufficiently early stage.

As a control group the author analyzed 417 cases of peritonitis following appendicitis and 183 cases of peritonitis following gynecological operations. In the appendicitis-peritonitis group 4 per cent had late obstruction, 7 per cent had considerable distress, and 89 per cent had no late symptoms. Of the gynecological cases, the frequency of obstruction was less than 1 per cent. The distress frequency was greatest in the fertile ages. Using these groups as a basis for comparison a total group of 477 patients with proved intestinal obstruction due to adhesions is analyzed. The mortality from the first operation for obstruction was approximately 50 per cent. In fully one-half of all cases a satisfactory result was obtained by operation. Among the survivors who were followed up, 14 per cent had a recurrence, 8 per cent still had considerable distress, and 68 per cent showed satisfactory results. Two per cent of those patients surviving a first operation for intestinal obstruction died of obstruction at some later date.

Males fall victim to obstruction more often than females, even when all the gynecological material is included for comparison. Males also have a higher mortality rate. Of the surgical operations preceding the operation for obstruction, those on the appendix have been the most frequent, gynecological laparotomies take second place, and hernial operations third. Mesenteric lymphadenitis gives rise to obstructive adhesions, but it is difficult to gauge the frequency of this etiology. The frequency of re-

currence of obstruction varies greatly with the etiology, and it is probable that the nature and severity of the original morbid process preceding the obstruction, whether this process has led to laparotomy or not, has a great bearing on the frequency of obstruction.

Cases of early obstruction have a higher mortality than the later groups. Interestingly enough, the diffuseness of the adhesions at the time of operation has little effect on the frequency of recurrence. Possibly the risk of recurrence diminishes when very diffuse adhesions are present, rather than individual bands. Voluntary or involuntary opening of the intestine during operation for obstruction probably has no considerable effect on the recurrence risk, although opening of the bowel does increase the mortality somewhat. The intervals of time between laparotomy and obstruction as well as between obstruction and recurrence show a proportional ratio.

At the second operation for obstruction, the mortality was 9 per cent, compared with a 50 per cent mortality at the first operation. Although the recurrence rate after the second operation is not appreciably different from that following the first, the results after further repeated operations become less and less encouraging.

In cases of recurrence of obstruction from adhesions following one or two previous laparotomies, scrupulous search should be made at the operation for foci of intraperitoneal infection. Special attention should be directed to the adnexae, the appendix, mesenteric glands, and Meckel's diverticulum. In some cases a short-circuited loop may be found. A ray examination of the lungs is indicated in all cases in which the etiology is not demonstrated with certainty. This is necessary because of the frequency of adhesions following tuberculous peritonitis. In laparotomies it is most essential to achieve the best possible peritonealization and to avoid opening the intestine unnecessarily. Enterocanostomosis is considered a suitable measure by which to evade obstructions when they are caught in a conglomerate mass of small intestinal loops. Resection for the purpose of preventing the formation of new adhesions is of doubtful value.

Considering the view advanced in this study that chronic infection plays an important role in the recurrence of adhesions, it does not seem likely that any considerable effect is to be expected from so-called adhesion-preventing agents introduced into the peritoneal cavity. On the other hand it might be possible to reduce the frequency of adhesions by combating acute and chronic infections through chemotherapy and antibiotic therapy. Measures which reduce the morbidity of tuberculosis also act in this direction.

HAROLD LAUTMAN, M.D.

Groen, J: Psychogenesis and Psychotherapy of Ulcerative Colitis. *Psychosomat. M.* 1947 9: 151

In 1930 Murray first called attention to the peculiarity of character of and the occurrence of psychologic conflict in patients with ulcerative colitis.

SURGERY OF THE ABDOMEN

These observations have been noted by others, including Groen who is a clinician without psycho-analytic training.

The author attempted through an elaborate biographical anamnesis to establish what had taken place in the emotional life of his patients before the onset of an initial or recurrent attack of ulcerative colitis. This method differs from psychoanalysis in that it does not rely too much on free association or dream analysis and is also less time consuming than analysis. It is the examiner who controls the conversation and sees that the history is related in a chronologic order. The examiner must objectify the findings. The patient should be made to feel that the sole purpose of the examiner is to understand and not to judge or condemn him.

The special peculiarities of character observed and described in detail by Groen are

- 1 A well developed intellect.
- 2 Carefulness and neatness, often exaggerated as striking features. The patients dislike vulgar or obscene expressions and hate coarse jokes. They are neat in their dress and choice of their clothes. Some of them have a flair for fashion in dress. They try to associate with people of a higher social status, thus acquiring a stamp of distinction and respectability. The women have a great sense of cleanliness, they are conscientious in the performance of their domestic duties and often continue the meticulous house work long after the disease has undermined their physical strength.
- 3 Extreme sensitiveness, even oversensitiveness. These patients are easily offended and do not get over things of minor importance. They feel ill treated and fret about it.
- 4 Hesitation and an unbalanced attitude toward the value of their own personality are frequently displayed. While on the one hand they may give the inferiority complex on the other they may give the impression that they have a full opinion of others. Inwardly they are full of criticism of the more they qualities. The more their confidence is gained the more they dare to criticize. A strong, but frequently hidden narcissism is apparent after a prolonged search about helping other people but actually they do nothing for anybody outside of their immediate circle. They hardly ever possess political or humanitarian ideals.
- 6 They have a passive attitude toward life but never do anything. They are usually ambitious but to a limited degree.
- 7 Fear is a dominant feature. In an emergency situation they usually retreat or fail. In any difficult situation they preferably choose the path of least resistance. This attitude may be hidden under a show of manly independence.
- 8 Lack of aggressive tendencies in behavior is present in most but not in all of these patients.
- 9 Love sympathy and affection and harmonious surroundings are sought for by these patients. If

they do not receive love from others they become utterly helpless and unhappy.

10. An exaggerated idealistic frequently naive and infantile conception of love. They think of love as a sublime adoration attachment, and harmony between husband and wife but consider the bodily sexual contact as something inferior. They cannot establish a normal harmony between their practical erotic and their ideal love life and consequently they seldom are capable of normal sexual relations. Many never marry or marry only after long hesitation. Loss of libido or impotence occurs frequently in male patients. Many of the married female patients have never experienced the onset of orgasm as frigidity frequently precedes the onset of colitis. These patients even the adult ones frequently practice masturbation which is in marked contradiction to the purity and idealism of their love ideal.

11 Abnormally strong fixation on the mother frequently combined with fear of the father is observed in all male patients. There just is no woman who can equal their mother. For some unexplained reason some of these male patients have an instinctive liking for elderly women. Their attitude toward other men is often reminiscent of the fear or hate they feel for their father.

Some female patients exhibit a strong fixation on the father and an aversion to their mother.

12 These patients repress and worry much more than is apparent, it is difficult to induce them to speak about their inner life. Sometimes they are ashamed of not being able to manage their conflicts themselves.

Individuals with a character structure just described may live undisturbed as long as their special wishes and desires are satisfied or as long as they live a sheltered life. However, this sheltered or special life may be easily upset. The mother may be withdrawn from the patient's fixation through death or otherwise so that he is left behind alone. The patient may marry a partner who is not willing to play the part of a mother substitute and this may result in a severe disappointment to him. In some cases things go wrong before marriage, as in the case of female patients reported by Murray. These women though entirely unfit for marriage had become engaged to be married. The fear of what would happen precipitates the onset of the disease. Groen noted in all of his patients that shortly before the outbreak of colitis there occurred a difficult situation in the former sheltered condition requiring an active solution that could not be effected by the patient. Sometimes the very fear of getting into a difficult situation had led to an inner conflict. This because of an external reason or reasons a situation arises with which the patient cannot cope and from which he cannot escape. This situation results from an emotional trauma which involves a combination of acute love loss and painful humiliation. It persists in the unconscious as long as the conflict is not solved. It is repressed because there is nobody to whom the

patient dares or can confess his difficulties. This state of bereavement and humiliation which the patient cannot solve by words or actions, and which he continues to conceal, precedes the outbreak of ulcerative colitis usually by barely a few days.

Treatment consists of 3 parts, namely an emotional catharsis and simple encouragement of the patient. These patients were told not to be ashamed of their great need for love and attachment. Their narcissism was gratified by making themselves superior to their father or teacher by virtue of their more refined inner life. Their lack of outward success was consoled by pointing out that the inner value of one's personality is appreciated only by a limited category of people. Groen concurred with his patients in the difference of opinion they had with their surroundings. As a result of this superficial type of treatment the colitis cleared up but the patients remained neurotic.

ROBERT TURNER, M.D.

Finocchiaro, R.: Clinico-Operative Study of 56 Patients with Tumors of the Colon (Coesiderazioni clinico-operatorie su 56 casi di operati per tumore del colon) *Ann. ital. chir.* 1947 24 45.

Of 56 cases of tumor of the colon 31 occurred in men and 25 in women. The regional distribution was as follows: cecum and ascending colon 22.6 per cent, transverse colon and flexures 20.7 per cent, descending colon 5.6 per cent and sigmoid 50.9 per cent. A radical operation was performed in 50 per cent of the cases, a palliative operation in 45 per cent and the remaining cases were inoperable. Of 36 patients who underwent a radical operation and could be followed up 19 or 73 per cent, were alive from 1 to 9 years after the intervention and were able to engage in the customary social activities.

The author stresses the necessity of a complete roentgenologic examination in every patient with symptoms of colitis because the typical symptoms of cancer may remain masked for a long time.

JOSEPH K. NARAT, M.D.

Lahey, Frank H.: Prognosis of Patients with Carcinoma of the Colon, Rectosigmoid, and Rectum. *Surg. Clin. N. America*, 1947 7 670.

The length of time that features such as alteration in bowel function, obstructive pain, change in caliber in the stools, and the presence of blood are associated with carcinoma of the colon and rectum, is employed to determine the prognosis.

Degrees of secondary anemia and apparent inoperability can be present in lesions of the right colon and still the patients may be found to be readily operable with 5 year nonrecurrence rates of gratifying percentages.

Annularity and canalization as shown by the roentgenogram in carcinomas of the colon and rectum are an indication of the lateness of the lesion.

The fact is stressed that cases of this type are of interest only in prophesying operability and should never lead one to be discouraged in exploring them because of the unpredictability of the rapidity of

growth and metastatic involvement which go so consistently with carcinoma of the colon and rectum.

CHARLES BARON, M.D.

Bacon, Harry E. and McGee, Lowrhn E.: Rectal Cancer. *J. Am. M. Ass.*, 1947 34: 553.

Vesical dysfunction subsequent to abdominoperineal proctosigmoidectomy for carcinoma of the rectum or sigmoid is not an incidental complication. It constitutes one of the major problems of management. Urinary retention occurs which if untreated or uncontrolled, results in dribbling of urinary overflow infection and urosepsis.

The authors believe that urinary retention following abdominoperineal proctosigmoidectomy unquestionably is due to trauma of varying nature and degree or more often to severance of the sympathetic and parasympathetic nerve fibers. These fibers constitute the inferior hypogastric or pelvic plexus and innervate the internal vesical sphincter and the detrusor urinae muscle. On removal of the plexus as interruption of the efferent and afferent stimuli to and from the bladder occurs which causes the bladder to become a hapless reservoir. The detrusor urinae is unable to contract because of the loss of the parasympathetic innervation.

In 7 of 244 patients upon whom an abdominoperineal proctosigmoidectomy was performed vesical atony occurred and normal urination was impossible. Of these 7 persons 5 are now well and urinate naturally. In 1 case the operation is too recent to permit evaluation the seventh patient became insane and committed suicide.

Maintenance of the bladder at complete rest until it has regained its ability to function normally preserves its musculature and prevents vesical atony. For this purpose an indwelling urethral catheter is preferred to cystostomy. The authors have established a definite preoperative and postoperative routine management. Preoperatively the urine is cultured at the time cystoscopy and cystometry are done. Vesical hypotonia should suggest the presence of an infiltrating lesion at or in the immediate vicinity of the ampulla of the rectum—the site of the pelvic neural plexus. Immediately before operation a catheter is inserted into the bladder.

Postoperatively the bladder is irrigated with an antiseptic solution twice daily. Cultures of the urine are taken on the fourth and tenth postoperative days and at the latter time cystometry is also done. If the patient is capable of exerting voluntary pressure of 70 cm. on the tenth day the catheter is removed. The absence or presence of residual urine is determined by the reinsertion of a catheter immediately after voiding. If more than 60 c.c. of residual urine are present, the catheter is retained 14-16 until the bladder is capable of more complete emptying. If the patient is unable to urinate after the removal of the catheter 200 mgm. of syntropin are administered orally 3 times daily to decrease the tone of the smooth muscle of the internal vesical sphincter. The administration of this medication

SURGERY OF THE ABDOMEN

is continued until normal urination occurs. Bacon and McCrea have not performed transurethral resection for this complication. Urinary retention may be transitory or may be present for days, weeks or months. If paralytic vesical atony develops the urinary retention may be permanent.

Impotence after proctosigmoidectomy occurred in 55.5 per cent of the cases in which the anal sphincter muscles were incised anteriorly whereas without division of these muscles the incidence of impotence was only 8.3 per cent. After the Miles type of abdominoperineal resection of the rectum the incidence of impotence is estimated at 95 per cent.

Positive urine cultures, while not always indicating the presence of cystitis nevertheless demand a constant alertness or guard against cystitis. It is believed that the preoperative administration of a sparsely soluble sulfonamide as a part of the routine preparation of the colon for major surgery exerts a bacteriostatic effect on organisms found in the urinary system.

D Allaines, F. and Devimeux, P.: Access to Rectum by Exclusive Sacral Route. Technique and Indications (L'abord du rectum par la voie sacrée pure. Technique et indications). *J. chir. Par.* 1947 63 181.

The region of the rectal ampulla between the levator muscles and the peritoneal cul-de-sac can be reached through the sacral route without great damage to the mucosal muscular and nerve tissues. This damage to the normal function of the involved intestinal segment allows the isolation of the peritoneal cul-de-sac, opening of the peritoneal artery lowering of the sigmoid and re-establishment of the continuity of the gut. The procedure is surprisingly well tolerated and this factor represents the greatest advantage of the method.

Whenever the resistance of the patient is good, the authors advocate a combined abdominoperineal approach if a malignancy is present. On the other hand if only a limited resection is contemplated on account of benign papillomas or those in an early stage of degeneration the sacral route is recommended. This method is useful when only the surface of the papillomas shows signs of malignant degeneration or when the patient is more than 70 years of age and has a cancer of slow evolution and a low tendency toward involvement of the glands.

The sacral route is useful in the removal of tumors situated too high to be reached through the anus and too low for the abdominal approach.

The authors emphasize the fact that the rectal zone which can be easily reached with the sacral approach, namely from 8 to 15 cm. from the anus, is the site of at least 50 per cent of all rectal tumors. For 8 days before the operation the patient is kept on a nonresidue diet and laxatives and enemas are administered daily. As a rule an iliac anus is established 15 days before the resection of a malignant tumor. A thorough abdominal exploration at the

time of the establishment of the artificial anus is strongly advised by the authors if a malignant lesion is present.

An excessive relaxation of the musculoaponeurotic planes caused by spinal anesthesia interferes with the proper anatomic repair and therefore the authors prefer general anesthesia with nitrous oxide. The patient is placed in a supine position. An inverted V incision is made. The sacrum is sectioned at a height which provides sufficient exposure of the lesion. Liberation of the rectum and extensation of the rectosigmoid segment are done in the customary manner.

JOSEPH K. NAKAT, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Martin J. D., Jr.: Wounds of the Liver. *Ann. Surg.* 1947 125 756.

Liver wounds, a major problem in abdominal wounds, have an over-all mortality of 10 per cent. Trauma of the liver is classified as direct or indirect. The magnitude of injury in direct trauma from penetrating missiles is dependent on the explosive effect of the missile. From moderate to massive hemorrhage can occur without damage to the main hepatic vessels and ducts. Nonpenetrating wounds have a lower incidence but may present identical pathologic findings. Complications are still drainage from the biliary system. Repair must be effected by removal of devitalized and necrotic tissue and later regeneration. During tissue autolysis further vascular and biliary ducts may be opened.

Systemic effects are often out of proportion to the degree of injury. At first shock may be profound and not equivalent to the blood loss. Later secondary manifestations of injury appear. These are concerned with blood loss, biliary extravasation, hepatocellular damage and occasionally associated renal dysfunction and are manifested by anemias, bile peritonitis and empyema, jaundice, lowered blood prothrombin and prothrombin formation.

The most serious complication, the so-called hepatorenal syndrome, more often follows extensive fibrinogen and prothrombin formation.

The most serious complication, the so-called hepatorenal syndrome, more often follows extensive fibrinogen and prothrombin formation.

It is desirable to ascertain the degree of functional impairment of the liver as this affords some index as to the extent of treatment and the prognosis.

Experiments were done using dogs and control determinations of galactose tolerance, bromsulphalein excretion, alkaline phosphatase activity in serum and prothrombin time were made before and after anesthesia with intravenous pentobarbital sodium. The dogs were then anesthetized and their livers subjected to varying degrees of trauma and then they were allowed to recover for study. The author observed that the liver had a very large functional reserve, as well as tremendous recuperative and regenerative powers.

In discussing the treatment the author states that suturing of the liver can seldom be done except in wounds near the periphery and hemorrhage is controlled in most instances by packing. Whenever damaged tissues are placed in apposition the process of repair is delayed and necrosis and sloughing occur before union is complete. The use of muscle grafts and newer hemostatic agents in the control of bleeding is discussed. As yet there is no ideal material available for the control of bleeding from a traumatized liver.

In the repair of liver wounds it is essential to close all wounds of the diaphragm in order to restore the integrity of the cavities and prevent the passage of bile and blood into the pleural sac, and to restore the mechanics of the respiratory system.

Ideal treatment would consist of débridement but this cannot be done in most cases until a better substance for controlling liver bleeding is perfected. At present, drainage must always be carried out and these drains are preferably placed through a stab wound. The general care of the liver wound is of paramount importance.

W. FORSTER MONTGOMERY M.D.

Sheinfeld, William: Cholecystectomy and Partial Hepatectomy for Carcinoma of the Gall Bladder with Local Liver Extension. *Surgery* 947 48.

A case of epidermoid carcinoma of the gall bladder with metastases localized to a resectable area of the liver is presented in detail. The feasibility and palliative value of liver resection for carcinoma of the gall bladder and local liver extension are discussed.

For comparison the results obtained with cholecystectomy for early carcinoma, or with simple exploration and biopsy for more advanced carcinoma are given.

From a survey of the cases collected liver resection when possible, appears to be of definite palliative value. However, the results in general are poor when compared with the results of radical surgery for carcinoma of other organs. JOHN J. MALONE, M.D.

Royer H., and Solari, A. V.: Cholangiography Performed with the Help of Peritoneoscopy. *Gastroenterology* 947 5 566.

In 1935 it was suggested that the gall bladder be injected with radiopaque material through a needle passed through the anterior abdominal wall the operator guiding this needle with the help of peritoneoscopy. The procedure had been carried out safely and with it bile had been removed from the gall bladder for study. It was suggested that this technique be used in certain puzzling cases in which ordinary cholecystography does not give a satisfactory answer to the diagnostic question.

For the peritoneoscopy a tube only 4 mm. in diameter is used. Obviously it is important to enter the abdominal cavity at the right spot so that the gall bladder can be visualized well. The best site is one a little below the edge of the liver and from 3 to 5

fingers breadth from the middle line. The examination is started with the patient on the roentgenologic table.

After the gall bladder has been visualized, the special needle used for the injection is pushed through the abdominal wall, 2 or 3 cm. away from the peritoneoscope. This needle consists of two parts, one, a tube 7 cm. long and 1 mm. in diameter and the other an inner hollow needle 17 cm. long and 1 mm. in diameter. Its lower end is narrowed to make a hollow needle 15 mm. long and 0.5 mm. in diameter. First the larger needle is pushed through the abdominal wall and then the smaller one goes through that. Then from 20 to 40 c.c. of an aqueous solution of some radiopaque substance such as diodrast is injected into the gall bladder. The double needle is then withdrawn and roentgenograms are taken in the usual way before and after a fatty meal.

With this method the authors have been able to make anatomical, physiological, pathological, and medical studies of the gall bladder and the hepatic and common ducts.

Little that was new could be learned about the anatomy of the gall bladder and cystic duct, but a curious observation was made in regard to the terminal end of the common duct. It appeared to be sharpened or beveled on one side. This appearance in the roentgenograms of the common duct was confirmed by postoperative cholangiography.

Most of the gall bladders studied physiologically showed traction in the region of the neck near the cystic duct. The gall bladder tends to contract uniformly without any change of shape.

When the gall bladder empties, part of the bile tends to go up into the hepatic duct and into the liver. This suggests a dyskinesia or failure of the sphincter of Oddi to relax.

In some of the cases it was easy to demonstrate even gall stones.

A contraindication to the use of this technique is acute inflammation in the region of the liver. So far there has been no accident with this technique.

In the presence of a puzzling jaundice, this technique can make possible an exact diagnosis.

HARRY W. FOST, M.D.

Cattell, Richard B.: Anastomosis of the Duct of Wirsung; Its Use in Palliative Operations for Cancer of the Head of the Pancreas. *Surg. Gyn. & Obstetrics*, 947 571-576.

Obstruction of the duct of Wirsung is a common finding in cancer of the head of the pancreas. It leads to marked disturbance of nutrition and causes digestive and bowel complaints. The earliest symptoms associated with obstruction of the pancreatic ducts are the direct result of a diminished amount of external pancreatic secretion. A change in bowel function is often the first symptom. Much intestinal gas may be present, with watery stools and intermittent diarrhea. The stool may become foamy and of increased bulk. General abdominal discomfort and indigestion are frequent complaints. Back

SURGERY OF THE ABDOMEN

pain may be the only localizing symptom. When the malignancy is primary in the duct of Wirsung or in the head of the pancreas the process may extend considerably before it causes obstructive jaundice.

It is possible to differentiate carcinoma of the ampulla from carcinoma of the head of the pancreas by reviewing the order of the onset of symptoms. Carcinoma that begins in the head of the pancreas and usually cause obstruction of the common bile duct. Santorini before obstruction of the common bile duct. Thus, the symptoms of indigestion, gas, bloating, diarrhea, and bulky foamy stools will be initial symptoms. Carcinoma of the ampulla of Vater on the contrary causes early obstruction of the common bile duct so that pruritus and jaundice are the first symptoms and only later as the pancreatic ducts are involved are other symptoms produced.

A new method of anastomosis of the duct of Wirsung to the jejunum in cases of inoperable carcinoma of the head of the pancreas is presented. This may be done as an open anastomosis over a T tube, or as a closed anastomosis of the duct of Wirsung in the intestinal tract, and may be followed by temporary dramatic relief of the digestive symptoms and a satisfactory gain in weight.

A case is reported to illustrate what may be accomplished by this procedure. Anastomosis of the duct of Wirsung as well as anastomosis of the biliary tract to the jejunum should be done whenever feared.

Dragstedt, Lester R. Clarke, James S. Harper, Paul V. Jr. Woodward, Edward R. and Torrey, E. Bruce: Supradiaphragmatic Section of the Vagus Nerves to the Stomach in Gastrojejunal Ulcer. *J. Thorac. Surg.*, 1947, 16, 230

This article is a continuation of observations made by the authors previously

The theoretical basis for section of the vagus nerves in the treatment of peptic ulcer may be summarized as follows

- 1 Current procedures in the management of peptic ulcer are designed to neutralize acid gastric juice or decrease its production.

- 2 When excessive continuous secretion of gastric juice is maintained in experimental animals peptic ulcers appear and progress.

- 3 An excessive continuous secretion of gastric juice occurs in most patients with peptic ulcer. This is most noticeable at night when ulcer bearing patients are found to secrete from 2 to 10 times as much acid as the nonulcer bearing patients.

- 4 Section of the vagus nerves to the stomach reduces the secretion of gastric juice in normal animals and in patients with peptic ulcer to an even greater degree. The psychic phase of gastric secretion is abolished by vagus section. Humoral and other factors influencing gastric secretion are present but the extent of their activity is not certain.

The night secretion in 105 vagotomized ulcer patients was reduced to one-seventh of the preoperative average.

The relief following vagotomy was so complete as to suggest that loss of pain sensation was produced, but introduction of 0.5 per cent hydrochloric acid into the stomach of vagotomized ulcer patients produced prompt recurrence of the preoperative pain.

The symptoms are relieved by vagotomy and the ulcers heal as measured by clinical standards as well as roentgen study.

In obstructive lesions complicating ulcer correct interpretation of postvagotomy complaints is important because the factor of obstruction may persist even though the ulcer heals. Ten gastrojejunal ulcers following gastroenterostomy or partial gastrectomy have healed under vagus section. Brief case reports of gastroduodenal ulcers and illustrative roentgenograms are appended.

HIRSH T. LANGSTON M.D.

GYNECOLOGY

UTERUS

Given, William P.: Carcinoma of the Cervix. *Am J Obst.*, 1947 53 947

The author reports a statistical analysis of 212 patients with cancer of the cervix uteri treated in the clinic of the Cornell University Medical College, Ithaca, and the New York Hospital, New York, New York, from 1933 through 1944. Of the total of 212 cases, 65 per cent were classed as stage 1 or stage 2 and 35 per cent were classed as stage 3 or stage 4 (League of Nations classification). Of the 212 patients seen from 1933 through 1940, 49, or 42.5 per cent, survived for 5 years or more.

There was no correlation between the histological classification of the cancer and the survival rate. Of far greater importance is the clinical classification in that those in stage 1 stand a good chance for survival while those in stage 4 are hopeless. Age and parity do not seem to affect the survival rate. Over 50 per cent of the patients were in the groups of stage 1 and stage 2 and had symptoms for 3 months or less. Ten per cent had no symptoms referable to the cancer when it was discovered. The author attributes this to careful inspection of the cervix and the routine biopsy of all cervical lesions including those not obviously malignant.

There were 12 cases of cancer of the cervical stump (3.8 per cent). The author believes that this high incidence lends argument to the use of total hysterectomy rather than the subtotal operation.

The patients were treated first by roentgen rays and then by radium. Roentgen therapy alone was used in a few of the advanced cases. Surgery was performed in only 6 cases.

The 4, 3, 2, and 1 year survival rates for the 97 patients seen from 1941 through 1944 are not appreciably different from the rates over the first period (1933 through 1940) despite the fact that in 1940 the radiation techniques were altered. There were 47 cases of late reactions to irradiation in the total group an incidence of 22.1 per cent. There were about twice as many reactions in the patients who were treated before 1940 as in those who were treated after 1940. This reduction in complications is attributed to improved technique in radiation therapy.

JOHN R. WOLFE, M.D.

Munnell, Equinn William: Total Hysterectomy. *Am J Obst.*, 1947 54 3

Should total hysterectomy be the routine procedure in the removal of the uterus for benign disease? To answer this question the author has surveyed 1708 hysterectomies performed on the gynecologic service of the Bellevue hospital, New York, New York. Of this number 1583 were subtotal and 215 were total hysterectomies.

The outstanding argument in favor of removal of the cervix at the time of hysterectomy has been that

it removes the possibility of subsequent development of carcinoma of the cervical stump. Less important arguments are the removal of the cervix as a possible cause of leucorrhea or focus of infection. The chief argument against the routine use of the total procedure for benign disease has been the higher mortality and morbidity associated with total hysterectomy.

The operative mortality among the patients having total hysterectomy was 1.32 per cent (5 cases) as compared to a mortality of 1.76 per cent for the group in whom a subtotal hysterectomy had been performed. The author is of the opinion that the deaths in the former were not due to the fact that a total rather than a subtotal operation was performed, but to complications that occur with either operation. Pulmonary embolus (in 3 cases), cerebral thrombosis, and paralytic ileus with shock were the causes of the 5 deaths.

There is a slight increase in morbidity with the total operation and patients will run a slightly higher temperature for a longer period of time also, catheterization is required less frequently. Distention is about the same. The chance of injury to the bladder or the ureters, or both, is increased by the total procedure, although the author believes that this danger can be avoided by the proper technique.

Sexual response in women is not significantly different with the cervical stump remaining than with the cervix removed. The cervix, uterus, and ovaries seem to have little to do with libido and sexual satisfaction. In cases in which there are changes following hysterectomy the cause is undoubtedly psychogenic.

Since the only valid argument against the routine use of the total hysterectomy is the slightly higher mortality rate associated with it, the author believes that this is not tenable when the number of deaths from the possibility of cancer developing in the cervical stump are considered. The prevention of cancer of the cervical stump is an adequate reason for performing total hysterectomy in benign cases as long as the operation does not introduce an element of extra danger to the patient. Any teaching service should consider it its duty to turn out gynecologic residents skilled in performing a total hysterectomy.

JOHN R. WOLFE, M.D.

ADnexAL AND PERIUTERINE CONDITIONS

Kieltsman, R.: Brenner Tumors of the Ovary (Ueber die Brennerschen Ovarialtumoren.) *Jcta obst. gynecol.* 1947 7 33.

A study of material collected at the gynecologic clinic of Allmanns Barnbordshuset, in Stockholm over a 14 year period from 1931 to 1944 revealed only 1 case of Brenner tumor of the ovary. The tumor had arisen in a 48 year old woman 18 years after the resection of both ovaries. At laparotomy a solid

stone hard, adherent tumor twice the size of a man's fist, was removed from the left parametrium. Grossly, the tumor was golden gray and on section showed a few pea to bean sized cavities beneath the capsule. Microscopically large epithelial masses were found lying in a supporting framework of well developed connective tissue. The epithelial cells were polygonal in shape with well defined nuclei and a large amount of protoplasm. The boundaries between individual cells were quite distinct. Most of the epithelial masses were solid but a few central cavities filled with homogeneous material were observed.

According to R. Meyer there are two types of Brenner tumor—solid tumors with or without cyst formation and tumors which lie in the walls of cysts. The present case belongs to the first group. The question of the frequency or rarity of Brenner tumors cannot be answered at the present time since they are of slow growth and may cause no clinical symptoms for a long time. Their occurrence can be determined only by systematic study of ovarian specimens. They may occur in young women and are not definitely bound to any hormonal or circulatory characteristic of a particular age group but they are more common in older women. The solid tumors vary in size from that of a sage grain to that of a man's head, are sharply demarcated from their surroundings by their color and because of their similar appearance, are easily confused with fibromas. Definite proof of recurrence or metastasis after removal has not been established. Of significance is the reported occurrence of new growths of various types in the second ovary. A hormonal influence on the endometrium and on the sexual function by Brenner tumors has not been proved although post climacteric and irregular bleeding has been reported by some authors.

There are several theories concerning the origin of the Brenner tumor. According to R. Meyer it arises from the Walthard cell focuses. Klein is of the opinion that it originates from the epoophoron. Schiller and Fauvet take the view that the tumor arises from the rete ovarii. These theories are not contradictory since the Walthard cell focuses, the epoophoron and the rete ovarii are of primary mesodermal origin. The presence of indifferent epithelium, mucous epithelium, serous epithelium and the plaster type of epithelium in the Brenner tumor can be explained by any of the three conceptions.

JOHN L. LINQUIST M D

Kletsman, R.: Horn Formation in Ovarian Carcinoma (Ueber Hornbildung in den Ovarialkarzinomen.) *Acta obst gyn scand* 1947 27 46.

Although ovarian carcinoma appears in manifold histologic forms with extreme variability in cell structure, flattened epithelium is rarely encountered microscopically. The case herewith reported is considered to be the eighteenth case in the literature. Up to the present time only 3 previous cases with flattened epithelium and horn formation in ovarian carcinoma have been reported with certainty and

because of the rarity of this condition the author reports the fourth case.

The patient was a 60 year old widow who had stopped menstruating 10 years previously and had had no subsequent genital bleeding. An abdominal tumor mass was palpated during a routine physical examination in connection with examination for heart trouble. There was no abdominal complaint and no edema of the lower extremities. At operation a partly solid and partly cystic tumor originating in the left ovary was found and removed. The cystic portion of the tumor contained about 1000 c.c. of fluid and its wall showed numerous papillary proliferations. The solid portion of the tumor was twice the size of a hen's egg and consisted in part of small pseudomucinous cysts and partly of solid tumor mass. Microscopic sections showed cylindrical cell carcinoma with glandlike formations, one to several cell layers in thickness and a sparse stroma. Here and there in the adenocarcinomatous portions were islands of flattened epithelium with pearl formation in a few places.

The diagnosis of this rare type of tumor depends upon microscopic study since any symptoms produced are of a general kind. Although in the present case no metastases could be demonstrated metastases have been observed in previously reported cases. The question of the histogenesis of flattened epithelium and horn formation in an ovarian tumor can be explained in several ways. The simplest explanation metastasis could not be established in the present case. The possibility of horn formation in a teratoma also suggests itself but in this case there was no evidence of teratogenous origin. The remaining explanation is horn development through metaplasia from an indifferent matrix. This explanation does not entirely answer the question but raises another question, namely that of the origin of these indifferent cells and their capacity to differentiate into flattened epithelium. It is assumed that a derivative of celomic epithelium provides the undifferentiated matrix. Histogenetically this tumor, like the Brenner tumor is supposed to arise from indifferent cells of mesodermal origin with special properties of differentiation.

MISCELLANEOUS

Bartlett, Marshall K.: The Surgical Treatment of Urinary Incontinence. *England J M.*, 1947 236 965

Up to the time the present study was undertaken at the Massachusetts General Hospital Boston the operative cure in patients with excretorial or stress incontinence was about 50 per cent. The usual procedure was repair of the anterior vaginal wall and a figure-of-eight or mattress stitch placed at the bladder neck.

The author believes that stress incontinence results when function of the involuntary sphincter mechanism is impaired owing to stretching and distortion of the bladder neck and proximal urethra.

This occurs after trauma that allows these structures to sag away from their normal positions behind the pubic arch. It is emphasized that although the voluntary sphincter may be damaged in the process, such damage is of little, if any importance in the production of stress incontinence.

The success of an operation for stress incontinence is considered therefore, to depend on the restoration of the bladder neck and urethra to their normal anatomic positions thus allowing the involuntary sphincter to resume its normal function. Various operative procedures having this principle are discussed.

Sixty three operations performed on 62 patients are reported. All patients complained of exertional urinary incontinence resulting from childbirth trauma. In the first 43 cases the technique described by Kennedy was followed. The vaginal mucosa is elevated from the bladder neck and posterior two-thirds of the urethra, and the dissection carried laterally under the pubic ramus until the urethra is entirely freed of its lateral attachments including any post-traumatic scar tissue that may be present. The urethra is then plicated in the midline to restore the function of the voluntary sphincter. In the last 21 cases of the series, stripping of the lateral attachments of the urethra from the pubic ramus was discontinued. It had been found that such dissection resulted often in considerable hemorrhage which was difficult to control and it was noted that the loss of these lateral structures might interfere with the replacement of the bladder neck and urethra in the normal positions.

The operations were performed during the period between 1939 and 1942. Forty-four patients (70 per cent) were cured. Of these 13 patients were followed up for an average period of 14 months, and 33 for an average period of 17 months.

L. JAMES TALBOT, M.D.

Walker, Louis M. and Huffman, John W.: Adenocarcinoma of the Female Urethra. A Review. *O. Bull. Northwestern Univ. M. School*, 1947 21: 25.

Twenty-seven cases of true adenocarcinoma of the female urethra and 5 cases of questionable adenocarcinoma of the female urethra were collected from the world's literature. Eleven cases in which the diagnosis of adenocarcinoma was uncertain were discussed in detail.

The origin of the tumor is thought to be in the paraurethral glands. The histologic picture is that of a glandular carcinoma reproducing the glandular arrangement of the source.

Analysis of the cases reveals that a "tumor" or nodule of the urethra, burning and frequency on urination and dysuria are the most common symptoms. A red mass at the urethral meatus is the most common finding of adenocarcinoma of the female urethra.

The final diagnosis depends on the histological findings in the excised tissues.

Prophylactically all urethral caruncles, adenomas, papillomas, and polyps should be removed and examined histologically. Most perurethral cysts should also be excised. Surgical excision was the treatment of choice of adenocarcinoma of the female urethra in earlier years. Most of the cases in the collected series were treated surgically. In 3 of the 17 some form of radiation followed excision. Irradiation was used in only 6 of the 23 cases in which treatment was discussed. It is, however, favored today because it usually preserves urinary continence and appears to be as effective as surgery in the treatment of this neoplasm. The interstitial application of radium to the lesion followed by bilateral dissection of the inguinal glands is also advocated.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Penttinen Karl: On the Wassermann and Kahn Reactions during Pregnancy. *Acta obst. gynaecol.* 1947 27 Supp. 3

This monograph is basically planned to ascertain the influence of pregnancy on serological reactions for syphilis. It can be recommended on the basis of its excellent statistical data. The essay seems to be designed primarily for those interested in biologic reactions particularly in relation to syphilis.

The author's work is extremely thorough with the exception that considerable international literature has necessarily been omitted because of the war. A majority of the references are to the Scandinavian English and American literature.

The author was primarily interested in the age old statements that (1) pregnancy causes an increased incidence of positive serologic reactions for syphilis and (2) that pregnancy exerts a beneficial effect i.e. a tendency toward a cure for syphilis.

Following a review of the literature, the author presents all of the techniques of investigation plus his own results. His investigations centered upon eight major questions. The first question considered was: How many false positive results were obtained during pregnancy? He concluded that false positive serology was no more common in pregnant patients than in the nonpregnant controlled group. He further believes that the false positives which are noted in pregnant women as well as in the nonpregnancy controlled group are due to technical variations rather than some factor associated with the pregnancy.

An attempt to discover a common factor in the group of patients showing false positive results failed to yield any specific relationship. However, the incidence of syphilis and positive serology among the unmarried group was found to be higher than in the married group as one might expect.

The author was next interested in the serologic factors which were characteristic of the group with false positive results. The results indicated that certain diseases will give an indeterminate percentage of positive Wassermann reaction. These diseases are listed in most of the standard textbooks, and almost invariably give weak quantitative reactions. In general they consist of new growths, virus infections, and other spirochetal diseases.

In respect to the technical differences, he noted a difference in results of the various laboratories. The obvious conclusion was that the greatest single factor in any biologic test depends upon the laboratory technique. It is important, therefore to use multiple laboratories and techniques in reaching a diagnosis of syphilis. In this respect the author concluded from his data that the Kahn verification test was of value in the diagnosis of syphilis but not of absolute significance.

The effect of the duration of pregnancy on biologic tests showed no significant statistical variation so that the hormonal and physiologic changes apparently have little or no effect on the reaction.

The moral of the essay is that all biologic tests may yield false results. In the present study the range of error was considered to be one in a thousand. When diagnosis depends upon biologic tests other means of diagnosis should be included and the test should be repeated several times and in different laboratories.

JAMES F. DONNELLY, M.D.

Belvederi C. and Morano, M.: Relation of the Arterial Retinal Pressure, Index of Frits, and Ocular Tone to the Modifications of the Fundus Oculi in Normal and Pathologic Pregnancy (*Pressione arteriosa retinica, indice di Frits e tono oculare in rapporto alle modificazioni del fundus nella gravidanza normale e patologica*). *Riv. Ital. ginec.* 1946 29 126.

This article is a continuation of a previous one in which the authors had concluded that a functional arterial spasm related to the arterial pressure occurs in the fundus of the eye during pregnancy. Continuation of the etiological factor leads to arterial spasm and vascular changes in other tissues which may become organic. These ocular phenomena, frequent in the primipara, are severe in the toxemias of pregnancy and very severe in eclampsia. The current opinion regarding these spastic changes in the eye is that they are an expression of a generalized involvement of the arterioles and precapillaries that takes place in all pregnancies which during the first half of a pregnancy may be due to hormonal changes and hypovagotonia, and during the second half to hyper sympatheticotonia. The added toxemia ocular in origin presents in the pathological pregnancy and intensifies the picture by acting directly on the arterioles and indirectly on the sympathetic system.

The correlation between the modification of the retinal vessels and the general arterial pressure has been noted by Mylius Klaffen, Wagener, Mussey and Masters. The authors claim that to these two factors which are important in evaluating alterations in the tissues of the pregnant woman (both normal and pathological) a third must be added i.e. the arterial pressure of the retinal vessels (A. P. R.).

In their studies they have made use of the Index of Frits. This represents the difference between the weight necessary to obtain the first arterial pulsation, and the weight necessary to occlude completely the artery in diastole. It is measured in grams of water the normal being below 10 grams. It is important to evaluate the elasticity of the arterial walls, it being higher in all cases in which changes in the coats of the vessels are present.

The importance of tonoscopy and tonometry in normal and pathological pregnancy is emphasized by

the authors who advise the measurement of ocular tension. Ocular tension, a product of local pressure and pressure of the aqueous humor parallels the changes in the arterial pressure and enables one to measure the A. P. R. in millimeters of mercury in stead of grams of water.

The authors became interested in the relation of the index of Frits to normal and pathological pregnancy and undertook observations on 95 cases of pregnancy. The study included general examination, urinalysis, general arterial pressure, index of Frits, ocular tension and examination of the fundus of the eye. The Riva Rocci sphygmomanometer was used for the arterial pressure, the ophthalmotometer of Baillart for the arterial pressure of the retina of the eye and the tonometer of Schiotz. The authors believe that there is a relation between the vascular changes in the fundus oculi, the general arterial pressure, the arterial pressure of the retina, the index of Frits, and the ocular tension. They believe also that the toxemias of pregnancy provoke a generalized spasm of the vessels which is transitory and functional in the beginning but later becomes permanent and organic and leads to irreversible changes in various organs, especially those well supplied with blood. They explain the exceptional case with a normal fundus oculi and an increased A. P. R. by saying that either the arterial spasm affects the capillaries and cannot be observed with the ophthalmoscope or that the case may be one of those reported also by Baillart in which there is a normal fundus oculi of the eye and a normal blood pressure but a local elevation of pressure, no albuminuria and a normal azotemia. They disproved the statement of Baillart that the increase in A. P. R. may be due to endocranial hypertension by making lumbar punctures in cases of neuroretinitis and in 5 cases with choroidoretinal separation, and reported that in these cases they did not find an increase in the endocranial pressure. A short functional spasm causes changes of no consequence in the affected vessels, but when the toxemias make this spasm permanent, sclerosis of the vessels, reduction in the size of the lumen, loss of elasticity of the walls and slowing of the blood stream occur. This increased resistance to the flow of blood brought about by the changes in the vessel walls, can be measured by the index of Frits, the normal being 10 grams with oscillations between 3 and 10 grams. This leads the authors to conclude that the index of Frits is of great importance in the determination of the elasticity of the vessels and is found to be normal in a normal pregnancy (a high normal found in only 4 cases) and greater than in the pathological pregnancy. This variation occurs *pari passu* with the severity of the changes in the fundus of the eye.

JOSEPH M. A. PARR, M.D.

Robinson, David; Hardy, Paul; and Hellman, L. M.: The Effect of Diphtheria on Pregnancy with a Report of 5 Cases. *Am J Obst.*, 947 53 079.

The occurrence of diphtheria during pregnancy or the puerperium is rare. This is essentially true be-

cause diphtheria is primarily a disease of the first decade of life, and because the general practice of active immunization has resulted in a decreasing incidence of this disease during the present century. Recently however for reasons not yet clear there has been an increase in the incidence of adult diphtheria. Thus, during the past year 4 patients with antenatal diphtheria have been observed. These women with a fifth patient delivered in 1907, comprise the cases reported and represent the total number of patients with diphtheria seen in the Obstetrical Clinic at the Johns Hopkins Hospital Baltimore in the past 50 years, during which time more than 50,000 deliveries occurred.

In the reviewed cases, pregnancy did not seem to alter the course of the disease in any way nor in the few cases reported by the author did the disease seem to alter the course or outcome of the pregnancy. All the mothers recovered from the disease and, following a normal labor, were spontaneously delivered of full term healthy infants free of the disease.

The treatment of diphtheria in the pregnant woman should be similar to that of diphtheria in the nonpregnant woman. Antitoxin is the most important single therapeutic agent. Secondary infections can be controlled by chemotherapy and antibiotics. Myocarditis, of course, should be treated by bed rest.

Although the reported rate of abortion in patients with diphtheria is 33 per cent, no interruption of pregnancy was observed in these cases, and none of them showed any premonitory signs of miscarriage. Abortion in acute infectious diseases with high fever however is not uncommon, and it is conceivable that inadequately treated diphtheria might result in a high rate of abortion.

No evidence was found that might indicate the passage of diphtheria toxin across the placental barrier.

JOHN R. WOLFE, M.D.

Bacon, Harry E. and Rows, Robert J.: Abdominoperineal Proctosigmoidectomy for Rectal Cancer Complicating Pregnancy; Report of 4 Cases. *South. M. J.* 947 40 471.

The literature on the subject of malignancy of the lower bowel complicating pregnancy was reviewed with a report of the authors' experience with 4 private patients.

The discussion involved a series of 23 cases in which operation was performed during pregnancy and 13 cases in which operation was instituted following abortion or delivery.

The symptoms in these cases are relatively the same as in any other malignancy of the lower bowel, but because they may be overshadowed by those of the pregnancy an added responsibility is placed upon the obstetrician. A careful history, digital examination, proctosigmoidoscopy, and opaque enema study are not contraindicated during pregnancy if warranted.

Pertinent to the management of this complication the following procedures may be recommended:

1 In early pregnancy (3 months or less) abdomino-perineal proctostigmoidectomy without colostomy and with preservation of the sphincter musculature or as a second choice, a Miles abdominoperineal excision especially when the lesion is less than 6 cm. from the anal margin with relative disregard to the pregnancy.

2 In the second trimester when the fetus is not viable and the size of the uterus would necessarily interfere with removal of the growth Porro section and resection simultaneously if the condition of the patient warrants such a procedure.

3 In the last trimester of pregnancy cesarean section and hysterectomy followed by removal of the cancerous bowel from 2 to 4 weeks later.

When the circumstances are ideal and the condition of the patient excellent, radical resection performed at the time of section may be justifiable.

CHARLES BARON M.D.

LABOR AND ITS COMPLICATIONS

Webster Augustus: *The Voorhees Bag*. 4m J Obst 1947 53 957

Since an increasing number of competent obstetricians have gone on record as condemning the use of the hydrostatic bag to a past era in obstetrics the author offers this survey of the use of the Voorhees bag in 164 cases among 28,000 deliveries from 1938 to 1944 inclusive at the Cook County Hospital in Chicago. The main indications for its use were to induce labor in toxemias and to control bleeding in placenta previa and premature separation of the placenta. It was used also in a miscellaneous group of cases consisting primarily of abnormal presentations and prolapse of the cord.

There were 168 infants (including 4 sets of twins) and the gross infant mortality was 85. Fifty-one of these babies were dead on admission of the mothers to the hospital. There were 34 stillbirths and neonatal deaths including 16 previsible babies. This gives a corrected mortality of 10.7 per cent.

A large percentage of the patients were not good risks for abdominal delivery. The author believes that it is not good obstetrical practice to subject a mother to the risk of abdominal surgery in the interim of a baby whose chances of survival are already minimal. It is better to deliver patients from below in all instances in which the viability of the infant is questionable.

It would seem that the use of the hydrostatic bag still has a limited place in obstetrics but no fixed policies can ever apply to its use. Careful consideration of each situation and good obstetrical judgment are essential if the best interests of both mother and child are to be observed.

JOHN R. WOLFE M.D.

Feeney J. K.: *Failed Forceps*. Irish J M Sc., 1947 No. 257 190.

Reports of 70,000 deliveries in three Dublin hospitals were examined by the author. From these records information was obtained on 191 cases in

which forceps had failed. In 77 of these failures occurred outside the hospital and the patients were subsequently admitted. In 44 cases failure occurred in the hospital.

Of the 77 patients outside the hospital who were subsequently admitted 38 were primigravidae. 34 had had 2 to 6 pregnancies and 5 had had 7 or more. The maternal mortality was 16.9 per cent. and fetal mortality 67.5 per cent. In the mothers who lived the complications were many the incidence of morbidity being 13 per cent. The author concludes from his analysis of these cases that the primary cause of the failure of forceps and of the subsequent complications was premature application of the forceps.

Of the 44 patients in whom failure of forceps occurred in the hospital 28 were primigravidae and 16 were multigravidae. The maternal mortality was 6.8 per cent. and the fetal mortality 43.2 per cent. The incidence of morbidity in the mothers who lived was 16 per cent. The author concludes from his analysis of these cases that the primary cause of failure of the forceps was a substitution of a trial examination, or both, and evaluation of the cephalopelvic relationship.

The conclusion reached is that a further effort should be made to reduce the incidence of failure of forceps. Better instruction of students and recently qualified men is believed to be the first logical step. A doctor should know not only when to apply for forceps but when not to do so.

L. JAMES TALBOT M.D.

Pitkärinen H.: *The Results of Treatment of Breech Births at the Midwifery School at Helsinki during the Years from 1934 to 1944* (Über die Behandlungsergebnisse bei Beckenendlagegeburten im Hebammeninstitut zu Helsinki in den Jahren 1934-1944). *Acta obst. gynec. scand.* 1946 75 Supp. 1

The author collects and evaluates statistics from 833 breech deliveries made in a 10 year period and including children weighing 600 gm. or more. The material includes 178 breech deliveries in 154 cases of twins. The over-all frequency of breech deliveries was 5.03 per cent. and of single deliveries alone, 4.01 per cent.

In 653 single breech births 136 of the infants (20.8 per cent) died. However 74 of these weighed less than 2,000 gm. With the mothers divided into 3 groups—primiparas under 30 years of age, primiparas over 30 years of age and multiparas—it was found that 43 (57.0 per cent) of the 74 deaths occurred in multiparas. Twenty-four (38.7 per cent) of the infants in the single breech deliveries weighing over 2,000 gm. were also in the multipara group. With manual aid in cases of infants weighing 2,000 gm. or over the reduced mortality amounted to 5.7 per cent. with extraction it was 24.2 per cent. No infant died as a result of cesarean section although 2 maternal deaths followed this operation.

In the twin deliveries in which one or both fetuses were presenting and born in breech presentation the

total mortality was 25 (14.04 per cent) 14 of these infants, however, weighed less than 2,000 gm. The maternal mortality in the twin deliveries was 0 per cent.

The author believes that the prognosis for the child grows less favorable with cephalopelvic disproportion and in cases in which labor is long especially when the labor pains are weak. He suggests that by intensifying prenatal care one can forestall premature deliveries, especially in multiparas. Extraction of the fetus is an emergency operation. Cesarean section should be utilized (1) when obvious disparity between the pelvis and fetal head exists, (2) when one expects a big child although a contracted pelvis is not a certainty and (3) when labor pains are weak and the labor long.

WARREN R. LANG, M.D.

Hunt, A. B., and DeVoe, R. W.: The Management of Delivery following Stillbirth from Previous Dystocia. *Am. J. Obst.*, 1947 53 81

The deliveries of 32 patients subsequent to stillbirth from dystocia in their primary pregnancies are reviewed. These patients were seen at the Mayo Clinic from January 1 1936 to July 1 1946. A gross fetal mortality rate of 1 fetal death in 36 deliveries, or 2.8 per cent was obtained. The infant in this case was dead in the uterus because of a severe toxemia of the mother on her admission to the hospital. There was no maternal mortality in this series.

When these data are added to those reported to years ago, it is found that 64 women had lost 71 babies from dystocia before this study was made. Subsequently they were delivered of 86 babies with 3 fetal deaths, a gross fetal mortality rate of 3.5 per cent. There was 1 maternal death early in the first series. The maternal mortality rate for subsequent deliveries was therefore slightly more than 1 per cent. Only 3 of the 64 women including the 1 that died are without normal living infants. One of these had a normal delivery but lost her infant some months later from nonobstetric causes. She is now pregnant and the chance for a living baby is excellent.

The opportunity for individual prenatal care, and examination and study of the safest method of delivery are most valuable in the care of these patients. In these cases the conduct of the first delivery subsequent to the stillbirth from dystocia seemed to determine the outcome in later deliveries. Patients who were delivered successfully through the pelvis continued to have this type of delivery and those who had to submit to abdominal delivery again required this management.

Carbonini, M.: The Prognosis in Cesarean Section in Pelvic Dystocia with Relation to Infection of the Genital Tract (La prognosi del taglio cesareo in rapporto al grado di purezza delle vie genitali nel caso di dystocia pelvica). *Ginecologia*, Tor 1947 23: 107

In a study of cesarean section between the years of 1935 and 1945 in which cases of pelvic dystocia, with or without genital infection, were compared as to

prognosis morbidity and mortality the author found the following factors influenced mortality: (1) the duration of labor (2) the time elapsed since rupture of the membranes, and (3) the febrile reaction during labor.

These cases were subdivided into 3 groups, namely clean contaminated and infected. The clean cases were those in which the cesarean section was done in the early stages of labor with intact membranes and in the absence of local pathological conditions such as vulval vaginitis or cervicitis with abnormal vaginal secretions. In this group the morbidity was 20.5 per cent, while the mortality rate was 0.69 per cent.

In the contaminated group were the cases in which the membranes had ruptured a few hours previously cases in which there had been repeated vaginal examinations, and cases with an elevated temperature, but not beyond 38°C. The morbidity rate was 50 per cent, while the mortality rate amounted to 2.38 per cent.

In the last group the infected cases, the temperature was above 38°C, and previous attempts to deliver the parturient through the vagina had been made. Putrefaction of the amniotic fluid was sometimes present with an increase in pulse frequency and leucocyte count, while the sedimentation rate exceeded 85 mm. This group carried the highest mortality and morbidity rate, having a 20 per cent mortality rate and a 80 per cent morbidity rate.

ARTHUR F. CIRIOZZA, M.D.

O'Connor, Cornelius T.: The Problem of the Repeat Cesarean Section—A Preliminary Study. *Am. J. Obst.*, 1947 53 914.

The mortality in repeat classical cesarean sections in this country is 3.5 per cent. This risk probably can be reduced to about 1.5 per cent. A review of similar experiences with the low cervical operation reveals a mortality of slightly over 1 per cent. In both procedures, second cesareans bulk large, with a much smaller number of third cesareans, and practically none beyond this. It is highly probable that the danger would have been greater were a larger number of fourth and fifth cesarean sections recorded.

The dangers of elective repeat section are both immediate (infection, ablation atony hemorrhage) and remote. The remote dangers of rupture of the uterine scar and intestinal adhesions are very marked after the classical section and exist to a much less degree after the low section. A conservative type of section with sterilization by various forms of tubal resection removes the dangers of rupture of the scar and risk inherent in another future cesarean section, but does not diminish the immediate mortality due to the procedure, nor the immediate and remote dangers from adhesions.

Evidence is presented that elective cesarean hysterectomy is simple to perform, causes less blood loss, has a smoother convalescence, and shows less morbidity than conservative repeat sections with or without tubal sterilization and in addition eliminates future dangers from a useless organ, the uterus.

This procedure should be given much more consideration as an elective procedure at repeat sections and should often be performed in the patient over 40 years of age in the presence of poor scars when the uterus does not contract perfectly, in the presence of marked adhesions, after the third or more classical section and in patients who are subject to severe grades of heart disease kidney disease or tuberculosis. Further experience may reveal it to be the procedure of choice routinely at or after the third section even when it is of the low type

JOHN R. WOLFF, M.D.

NEWBORN

Acklen Henry S. Jr.: Fetal Mortality in Cesarean Section. *Am J Obst* 1947 53 937

The author reports the results of a survey of the fetal deaths associated with cesarean section during the last 10 years at the Methodist Hospital Brooklyn New York. In 1938 he reported the results of a similar survey which showed a high fetal mortality (5.9 per cent). In his latest series of cases the maternal mortality was reduced from 3.18 per cent to 0.65 per cent while the fetal mortality remained about the same (4.9 per cent).

Prematurity is the greatest single cause of fetal mortality. It occurs most often in conjunction with placenta previa. The policy of delay in the active treatment of placenta previa might carry more in favor of closer to term but widespread advocacy of this policy would endanger the present low maternal mortality. In the event of maternal hemorrhage the mother should have early blood transfusion and pure oxygen should be administered to combat fetal anoxia. These procedures should be carried out even though there be no apparent need of them by the mother.

If cesarean section is indicated in patients with abnormal presentation operation should be performed early. Regional anesthesia prevents one cause of fetal anoxia and should be widely used in cesarean section. Spinal anesthesia produces greater relaxation thereby aiding delivery and lessening trauma to the baby.

In the present series of cases the fetal mortality associated with cesarean section was higher than that for vaginal delivery. The author pleads for an increase in the autopsies on stillbirths and neonatal deaths in the interest of accurate diagnosis.

JOHN R. WOLFF, M.D.

Rodriguez Velasco, Anibal: Vulvar Postpartum Chorioepithelioma (Corio-epithelioma vulvar primario post-partum). *Bolet. Soc. chilena obst. ginec.* 1946 11 312

Chorioepithelioma is without doubt the most malignant tumor of the genital tract. The author describes 2 cases: the first occurred in a woman who had passed the menopause and who had never been pregnant, while the second was of a vulvar ectopic postpartum type occurring in a 29 year old female who had had 3 pregnancies. The last terminated at full term with a normal delivery and no placental changes. One month post partum the patient had a severe vaginal hemorrhage from an eroded nodule beneath and to the left of the urinary meatus. Two months later she had a violent vaginal hemorrhage from an eroded zone in the left hemivulva, which looked like a black ulcerated tumor mass with multiple violet colored masses, some hard and others soft and easily enucleated. The Freedman test was strongly positive and the roentgenogram of the chest showed multiple metastases to the lungs. Biopsy of the vaginal lesion revealed a metastasis of a chorion epithelioma. The author attempted surgical removal of the tumor. Autopsy revealed metastasis to the brain, lungs, liver, spleen, and vagina.

The advantages of biopsies and biological titrations for diagnosis are stressed and the author favors extensive abdominal surgery even though metastases have spread. He advises deep x ray therapy for the metastases.

MISCELLANEOUS

Glirardi V.: Influence of the Vitamin B Complex on Lactation (Influenza del complesso vitaminico B sulla secrezione lattica della donna). *Riv. ostet. ginec.* 1946 1 146

Thirty two women in the puerperium were divided into four groups and treated respectively with (1) total vitamin B complex, (2) vitamin B and nicotina mide, (3) vitamin B in massive doses and (4) vitamins B₁ and B₂. The subjects were given similar diets, and examination of the milk was done under standard conditions.

On the basis of the volume and the fat content, it was concluded that the administration of vitamin B complex, particularly B₁ and B₂, exercised a favorable effect upon lactation.

Chemical and physiological bases for these findings are discussed.

EDITH B. FARMERWORTH, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Abelhouse, Benjamin S.: Crossed Ectopia with Fusion. Review of the Literature and a Report of 4 Cases. *Am J Surg* 1947 73 658.

The distinguishing feature of crossed ectopia with fusion is the congenital transposition of one kidney to the opposite side with fusion of the other kidney to the other side. The author has collected 47 new cases of crossed ectopia with fusion and has added 4 personal cases which brings the total of reported cases to 337. This anomaly is encountered about once in every 7,500 autopsies.

There are 6 anatomical varieties of this anomaly which are presented in the order of relative frequency (1) unilateral fused kidney with the ectopic kidney in an inferior position (2) sigmoid kidney (3) "L" kidney (4) disc kidney (5) lump kidney, and (6) unilateral fused kidney with the ectopic kidney in a superior position. The anomaly has been found at various levels from the lower thoracic vertebrae to a position deep in the true pelvis. The age and sex of the patient with this anomaly apparently have little significance from an embryological or clinical standpoint. In the 337 cases reviewed the sex ratio was 4 males to 3 females. The majority of the cases occurred in individuals under the age of 50 years, particularly in the third, fourth, and fifth decades of life. There is no syndrome typical of this anomaly. The outstanding symptoms are pain and a palpable mass which are frequently accompanied by various urinary symptoms or abnormal urinary findings.

The diagnosis was made at autopsy in 120 cases, particularly in the early reports and in children dying of various diseases. An accurate clinical diagnosis was made by urographic methods in 134 cases and at operation in 37 cases. The most important diagnostic method is retrograde pyelography. Intravenous pyelography was employed in 15 cases and yielded positive information in 5 cases. Failure to make an accurate preoperative diagnosis may lead to dire results.

This anomaly is accompanied by various renal diseases, particularly infection and dilatation of the pelvis. The crossed ectopic kidney is more susceptible to these pathological lesions than the noncrossed kidney. The surgical treatment may be conservative or radical and is governed by the nature of the pathological lesion, the extent of fusion deformity and the condition of the patient. In pregnancy dystocia is more likely to occur when the fusion anomaly is located at or below the promontory of the sacrum. Normal labor is to be expected when the anomaly lies above this level. Conservative or palliative surgery can be undertaken in this anomaly with as little risk as in cases with a normally formed kidney. Symphyctomy combined with nephropexy may be employed with good results in cases presenting no significant

pathological lesions but accompanied by pain of renal origin. Radical operation consists of removal of one renal component of the fusion anomaly, i.e., heminephrectomy. It is a safe surgical procedure which can be performed by the well trained genitourinary surgeon with great facility and minimal shock in the absence of unusual anatomical or pathological complications.

JOSEPH E. MAURER, M.D.

Bianchi, F.: Intrarenal Lipomas with the Description of a Case of Lipomyeloblastoma (Sul lipomi intrarenali con descrizione di un caso di lipomyeloblastoma) *Arch. Ital. urol* 1946 830.

Because of the rarity of lipomyeloblastoma and the difficulty of differentiating an intrarenal lipoma from a retroperitoneal neoplasm, this case is presented.

The patient was a female of 58 years. At 14 years of age she had a ptosis of both kidneys. Years later she experienced acute and continuous pain in the dorsolumbar region for which a body plaster cast was applied for a period of 8 months with no relief. From 10 to 15 months before the patient was seen by the author she had become aware of a tumor mass in the right lumbar region which gradually enlarged. A week before she entered the hospital she had experienced a sharp pain in the right lumbar area. No disturbance in urination was present but a brief painless hematuria had occurred many years ago. In the past few months she had lost 13 pounds in weight. The tumor was hard, irregular, tender on palpation, and slightly movable. It deformed the right lumbar region.

Microscopic analysis of the urine showed a few red blood cells and many uric acid crystals.

The azotemia was elevated to 0.66 per cent, however after a diet on milk and vegetables it was lowered to 0.35 per cent.

The flat plate x-ray was negative, but pyelography revealed a large kidney with irregular calices and a ureter deviated toward the midline from pressure by the tumor.

A diagnosis of renal tumor on the right side was made, and the patient underwent surgery. The superior pole of the kidney was markedly enlarged and adherent to the peritoneum also the adipose capsule was firmly attached to the renal capsule.

Gross examination of the specimen showed it to be of brown color and weighing 1,460 gm. with the enlargement mainly at the superior pole. Its dimensions were 33 by 2 by 2 cm., and on cross section about two-thirds of the mass was yellowish in appearance and lobulated. The consistency was soft and somewhat elastic, being not much dissimilar from normal adipose tissue.

Microscopic examination revealed fat cells with empty areoles similar to normal adipose tissue with the exception of the areoles of nonuniform dimen-

ations. Some cells were rich in cytoplasm with giant nuclei others presented nuclei of different form. The richness of the cytoplasm the size of the nuclei the presence of pluri-nucleate masses and especially the wide nucleated fibers made the author suspect myeloblastic tissue.

The patient recovered and was still well after 2 years.

ARTHUR F. CIPOLLA, M.D.

Davis, David M. : Ureteral Obstruction: Recent Advances in Its Embryology Nosology and Surgery. *Brit. J. Urol.*, 1947 19 71

It seems only a short time since conservative surgery for hydronephrosis was regarded by everyone with doubt and misgiving. The advance in this field has occurred gradually but unremittingly and now in retrospect the change in the whole picture is spectacular. It may now be asserted that operations for the cure of hydronephrosis are very reliable and that the results are as certainly predictable as in any other type of surgery. This fact necessitates drastic changes in the concept of the proper program of treatment in such cases. Nephrectomy in the future must be reserved for those cases in which the damage is extreme and irreparable.

This very gratifying situation has been brought about by the following factors: (1) increased knowledge of the underlying pathology (2) better methods of diagnosis particularly intravenous urography which can be employed by every medical practitioner (3) simpler operative methods (4) increased knowledge of the mechanical factors important in the postoperative period—namely, splinting kidney drainage and the prevention of sanding (5) the use of sulfonamides and penicillin to combat and prevent infection.

JOHN A. LOEY, M.D.

Figueron Alcorta L., Massolo O. and Molina Luis R. Spontaneous Rupture of the Ureter (La ruptura espontánea del uréter). *Rev. argent. urol.* 1945 14 335

Spontaneous rupture of the ureter is a rare affection as the work of Surrao presents only 8 cases which were observed up to the year 1936. Nearly all cases are due to trauma, either external or internal and pyeloureteral lithiasis is the cause of the trauma in the majority of the cases. Although the papules in the calix are often the site for rupture the narrowings of the ureters are the most common sites and sometimes pyelographic manipulation is an etiological factor.

Two cases of spontaneous rupture are reported, both were due to lithiasis. The first patient had severe nephritic colic with an elevated temperature. Palpation revealed exquisite tenderness on the affected side with a tumor mass similar in character to an infected hydronephrosis or pyonephrosis. X-rays showed 3 small shadows within the renal zone, related to other calculi. An ascending pyelogram revealed the sodium iodide diffused in the perirenal tissues. A lumbotomy was done which released a frank pyogenic greenish staphylococcic collection.

Two days later the patient passed a calculus the size of an olive seed. Subsequent X-rays revealed no remaining calculi. The patient recovered and was well 5 years after the initial onset of the condition.

The second patient had repeated attacks of renal colic dating back 15 years and also had passed gravel and a calculus. Fifteen days before entering the hospital he had renal colic with hematuria and high fever. However on admission the preceding symptoms had subsided. X-rays revealed a globular shadow with a line of phleboliths in the pelvis. A ureteral pyelogram of the right side with the use of a sound showed discrete dilatation of the ureter and a ureteral injection permitted diffusion of the contrast media to the perinephros. X-rays taken 3 days later showed complete elimination of the iodine. A few days later another ascending ureteral pyelogram with a Chevasse sound was taken and air was seen to escape into the perinephritic space. The last X-ray showed the ureteral fistula to be closed with no escape of iodine. In spite of all the manipulation the temperature did not rise and the patient was discharged 5 days after admission.

In both cases the process was revealed by pyelographic studies. In the infectious suppurative pyeloureteral process the authors performed a lumbotomy while in the second case the excellent condition of the patient led to expectant treatment.

ARTHUR F. CIPOLLA, M.D.

Burns, Edgar Kiltredge, W. E. and Hyman Jack: Bilateral Cutaneous Ureterostomy 18 Years After Ureterosigmoidostomy for Exstrophy of the Bladder. *Ann. Surg.*, 1947 125 788.

The present tendency in the treatment of exstrophy of the bladder is to perform ureterosigmoidostomy early preferably during the first 6 months of life before the bacteriological flora of the bowel become too varied and pathologic. The age at which the operation is performed does not of course eliminate such mechanical factors as angulation and stricture formation at the site of anastomosis factors which most likely account for the majority of complications encountered in these cases. The authors have reviewed the literature combining the reports of 13 authors and collecting 41 cases of ureterointestinal anastomosis in which the patients were alive from 6 to 44 years after operation. Thirty-eight per cent were reported as well while in the remaining 62 per cent the following conditions were encountered: hydronephrosis, loss of function of one kidney, renal calculi, calculus pyonephrosis requiring nephrectomy and infected hydronephrosis requiring nephrostomy.

The authors suggest that the life expectancy of certain of these patients may be increased by ureterocutaneous anastomosis. They present the case of a 30 year old white male who had undergone bilateral ureterosigmoidostomy at the age of 12 years. Examination revealed bilateral hydronephrosis and unilateral renal calculus. The patient had evidence of a renal infection which could not be controlled by

urinary antiseptics. Bilateral cutaneous ureterostomy was performed by the authors at the Ochsner Clinic, New Orleans, Louisiana and the patient made a remarkable recovery gaining in weight and health. The renal function was much improved.

The authors emphasize the following principles in cutaneous ureterostomy (1) freeing the ureter from its bed without stripping in order to avoid injury to its blood supply (2) allowing the ureter to project 4 or 5 cm. beyond the skin margin without angulation or tension, (3) closing the wound lightly around the stump without placing sutures in the ureteral wall and (4) using a loosely fitting catheter during the immediate postoperative period.

JOSEPH E. MAURER, M.D.

BLADDER, URETHRA, AND PENIS

Cifuentes, L.: Vaginal Epithelium in Female Trigonitis. *J. Urol. Balt.*, 1947 57 1028.

The author describes a variation of the trigonal mucosa at its extremity near the vesical neck. These areas are variable in size, their color ranging from white to whitish gray. This abnormality is most often limited to the midline but may extend over the anterior two-thirds of the trigone. The posterior margin is always clear cut and irregular. The author believes that this occurs in over half of the adult women but that it is less common in elderly women however a precise statistical study is being undertaken to determine the incidence in various age groups.

In 30 instances biopsies were taken. The cellular morphology was different in these areas as compared to a normal bladder since the cells were larger, and the epithelial thickness greater. The epithelial picture simulates that of vaginal epithelium, with an appreciable glycogen content, epithelium not completely keratinized on the surface, well formed papillae, and often intraepithelial cornification.

The distinct difference between atypical areas of flat stratified epithelium and trigonitis is emphasized. Trigonitis is strictly an inflammatory process. The epithelial abnormality is asymptomatic without abnormal urine findings while trigonitis is symptomatic with a cellular picture in the urine of inflammation. The removal of septic foci (tonsillectomy) will often prove spectacular in the disappearance of a true exudative trigonitis. ROBERT LACK, JR., M.D.

Jewett, Hugh J.: Carcinoma of the Bladder. *J. Am. Med. Ass.* 947 34 496.

Pre-existing metastases pre-existing extravascular extension, intercurrent complications, and incomplete destruction or extirpation of the primary neoplasm are responsible for the current low survival rate in patients with infiltrating carcinoma of the urinary bladder. The existence of metastasis or extravascular extension of the growth means an advanced stage of the neoplasm which is incurable by any of the known methods of therapy. Low curability is generally caused by (1) late diagnosis (50 per cent of patients

have symptoms longer than one year while 30 per cent of patients have symptoms for from 2 weeks to 6 months) and (2) inefficiency of treatment which allows a tumor without extravascular spread to persist in the wall of the bladder until it has extended extravascularly or metastasized. It is hoped that late diagnosis will be avoided by education of the laity and members of the medical profession. Inefficiency of treatment will be recognized earlier and oftener when the importance of an accurate appraisal of the entire pathologic picture is more fully appreciated.

Pathologically the tumors fall into 3 major categories: papillary epidermoid and undifferentiated carcinoma (the poorly differentiated varieties in the papillary and epidermoid groups should be recorded). It should be borne in mind that a section showing a well differentiated carcinoma in one area may show undifferentiated cells in another area of the same tumor. The cellular appearance alone of an infiltrating carcinoma indicates neither the presence nor the absence of metastasis. However when the neoplasm is deeply infiltrating the poorly differentiated papillary carcinomas metastasize in nearly 50 per cent of the cases, the poorly differentiated epidermoid carcinomas in at least three-fourths, and the undifferentiated carcinomas in practically all the cases.

Cystoscopy biopsy and bimanual palpation are important specific diagnostic procedures. A properly taken biopsy specimen is a good sized piece of tissue that includes some muscularis, removed preferably with a cold rongeur. In pedunculated tumors the piece should be taken immediately beneath the base of the pedicle. The inclusion of some muscularis establishes the presence or absence of infiltration as well as the diagnosis of the growth. Biopsy alone does not furnish a clue to the prognosis because the removed piece of tissue is a small part of the whole neoplasm.

Bimanual palpation will detect the stony, hard induration encountered in over 80 per cent of cases of deeply infiltrating tumors. This examination will segregate this group of tumors from the superficially infiltrating tumors which practically never cause stony induration.

Deeply infiltrating tumors are associated with a high incidence of metastasis. Where these tumors are poorly differentiated, they probably have metastasized in nearly all cases. In superficially infiltrating tumors the incidence of metastasis is low except perhaps in the case of undifferentiated carcinomas.

In the absence of metastasis and extravascular extension, a good prognosis will depend on complete destruction or extirpation of the neoplasm and adequate treatment of any future recurrence.

ROBERT TURELL, M.D.

Marshall, Victor F.: Cancer of the Bladder. *J. Am. Med. Ass.* 947 34 50.

The author compares the results obtained from radiation therapy with those of surgery for cancer of the urinary bladder. After a fairly extensive trial the results of radiation therapy with the armamentarium now available have been found to be generally poor.

The fact that obliteration of the endolymphatic duct to this extent did not appreciably affect the volume of endolymph in the remainder of the system in a period of 3½ months rules out the hypothesis that hydrocephalus of the labyrinth can be attributed to impairment of function of this structure.

JOHN F. DUNN, M.D.

NECK

Seidlin, S. M., Marinelli, L. D., and Oshry, E.: Radioactive Iodine Therapy. *J. Am. Med. Ass.* 1946 13: 838.

A patient was completely thyroidectomized for malignant adenoma in 1923 and 15 years later hyperthyroidism and severe back pain developed. In October 1939 a pulsating metastatic thyroid adenocarcinoma was removed from the region of the twelfth thoracic vertebra. The hyperthyroidism continued to progress for the next 3 years, and metastases were demonstrated with x-rays in the lungs, the right femur, the second rib on the left side, the left ilium, and the skull. Roentgenological therapy was ineffective. In March, 1943 a tracer dose of radioiodine was shown to be taken up by all the metastases. Between May and August, 1943 a total of 1.2 milluries of I^{131} (half-life 13.6 hours) and 30.5 milluries of I^{131} (half-life 8 days), prepared in a cyclotron by bombardment of tellurium with deuterons, was given as sodium iodide in water. The estimated dose to the tumors was 10,600 equivalent r and to the blood 70 equivalent r.

Most of the radioactive iodine was taken up by the metastases. Time concentration curves were constructed for the tumor, blood, and urine. Additional treatment in April, 1944 and March 1945 resulted in relief of the pain and the patient was in good condition at the time of the report.

CLETON H. THURMAN, M.D.

Bartels, E. C., and Bell, G. O.: Thioracil. Preoperative Use in 400 Patients with Severe Hyperthyroidism. *West. J. Surg.* 1947 55: 39.

Thioracil was used during the last 3 years in the preoperative treatment of 400 patients with severe hyperthyroidism. These patients represent about 35 per cent of all patients having thyroidectomy for hyperthyroidism. All patients were not prepared with thioracil therapy. Three hundred thirty-eight cases were classified as primary hyperthyroidism, and 62 were classified as toxic adenomatous goiters. Table I shows the breakdown of evidence of severe hyperthyroidism. Table II shows a breakdown of the significant complicating diseases in 400 cases.

Thioracil was administered in a total daily dose of 0.6 gr. It was found that full control of hyperthyroidism is essential before thyroidectomy. If full does not take place, then any of the usual may arise. Thioracil treatment should be individualized. Roughly it was found that 1 day of thioracil treatment was needed for each percent age elevation in the basal metabolic rate. A patient

with primary hyperthyroidism of short duration, and one who has had no iodine, will have a daily drop of about 1.3 per cent in basal metabolism. Patients with primary hyperthyroidism of long duration or of short duration who have received iodine therapy, will have a daily drop of 1 per cent in basal metabolic rate.

Patients with adenomatous goiters, who have had no previous iodine therapy, will show a 0.64 daily drop in the basal metabolic rate. Patients with adenomatous goiters who have had previous iodine therapy will show a 0.45 daily drop in the basal metabolic rate. At surgery the thyroid gland was found to be very soft and vascular when only thioracil had been given preoperatively. To overcome this difficulty Lugol's solution was combined with thioracil, thus making the surgery more satisfactory. Table III shows the reaction to thioracil in 400 cases. A total of 35 cases showed white blood cell depression, fever, skin eruption, edema of the skin or swelling of the salivary glands. A chart is included, which shows the time of reaction to thioracil. The time of onset of reactions varied widely except for the fever reaction which occurred on the ninth or tenth day. Both total and differential counts are necessary and these are repeated at 7 to 10 day intervals during thioracil therapy. When agranulocytosis develops, energetic penicillin treatment is advised as protection against infection during the vulnerable period. Of 13 patients sensitive to thioracil, 11 tolerated thiobutyl. The advantages of thioracil preparation are that the patient is restored to a normal state of health for thyroidectomy, the need of multiple stage operations is eliminated, and the treatment has practically abolished mortality. Also, the postoperative course of the thioracil-treated patient is less stormy.

Two hundred sixty-six patients have been followed from 6 months to 3 years following thyroidectomy. Among these there have been 5 cases of recurrent hyperthyroidism, 8 patients have persistent postoperative myxedema, there have been 3 cases of unilateral cord paralysis and 3 patients have developed progressive exophthalmos. There was 1 postoperative death and 1 death from agranulocytosis due to thioracil, a mortality of 0.5 per cent.

RICHARD J. BENNETT, JR., M.D.

Ross, E., and McConnell, J.: Thioracil in Thyrotoxicosis—Results of Prolonged Treatment in 35 Cases. *Am. J. Med. Sci.* 1947 13: 74.

The authors' patients were under observation for from 10 to 30 months. On the basis of results, they were grouped as follows:

Group 1 includes 16 patients in whom sustained remission followed the cessation of thioracil therapy. There were 15 females and 1 male. Three patients were in the second decade of life, 1 patient was in the third, 3 patients in the fourth, 6 in the fifth, 3 in the sixth and 1 patient in the seventh decade. Thirteen patients were under observation for 1 year or more, and 8 for more than 2 years. There were 15 with diffuse goiter and 1 with nodular goiter. The longest period of treatment with thioracil was 10.6 months.

however it is believed that this method of treatment should not be discarded because of the cure obtained in the occasional case and the palliation it affords, especially in the late metastasis. On the other hand surgical methods (mainly resection of the bladder with or without ureteral reimplantation or total excision of the bladder with diversion of the urinary stream, transplantation of the ureters to the skin or uretero-intestinal anastomosis) will result at the least, in a small increase of 5 year successful results, a moderate improvement in average survival and a really significant amount of palliation as compared with the results obtained by radiation methods.

In some cases it is advantageous to use both forms of therapy particularly after the obvious failure of one.

ROBERT TURNER, M.D.

Lewis, L. G. : Repair of Rectourethral Fistulas. *J Urol.*, Balt. 1947 57 1173.

Lewis employed the Whitehead principle of advancement of the rectum in the successful repair of 13 patients with rectourethral fistula following wound ing by combat missiles. The communications were between the membranous or prostatic urethra and the rectum in all cases. In 5 patients multiple communicating fistulas were present. In all but 1 case, suprapubic cystostomy and abdominal colostomy had been performed shortly after injury.

The patient is placed on the operating table in an exaggerated lithotomy or perineal position spinal anesthesia is employed. For repair of a simple fistula with an intact anal sphincter an annular incision is made around the anus at the mucocutaneous juncture and the entire operative procedure is carried out through the dilated anal sphincter. When the anus is ablated the scar is completely excised and a plastic closure is made. The anal mucosa is carefully dissected from the external anal sphincter, the entire rectum is freed laterally posteriorly and anteriorly and the fistulous tract is divided until the rectum can be brought down without tension to bring the rectal fistulous opening outside of the anal margin. The middle hemorrhoidal vessels must be divided and ligated. It was found necessary in all instances to free the rectum beyond the prostate to the base of the bladder. Then the urethral fistula is excised widely.

Several No. 1 mattress sutures of No. 1 chromic catgut are used to close the urethral defect. Except in cases of urethral stenosis (in which the scar surrounding the urethra is excised) no retention catheter is used. Most important, 6 stay sutures between the rectal wall and the perineal walls, 1 inch above the anal sphincter, must be inserted.

A Penrose drain is brought out posteriorly to the new anal margin or through a posterior stab wound. The rectum excess is excised and the anal mucosa is sutured to the marginal skin with interrupted silk. The levator ani muscles are sutured together in the midline anterior to the rectum when possible, but no attempt to interpose perineal tissue between the urethra and rectum is made otherwise.

DAVID ROSENBLUM, M.D.

Burnier E.M.P. Cancer of the Penis (Cancer do penis) *Rev. brasil. cir.*, 1946, 15 513 1947 16 43 89.

Of 3 500 patients with cancer treated at the National Cancer Dispensary 73, or 2 per cent, had a malignant tumor of the penis. If only operable cases are considered the percentage rises to 5 per cent. Contrary to the statement that cancer is a disease of old age cancer of the penis usually occurs in middle age at the height of sexual activity. Fifty three and four tenths per cent of the author's material were men under 50 years of age.

Veneral diseases, trauma erythroplasia (corresponding to leucoplasia of the oral cavity) and congenital phimosis have been mentioned in the literature as causative factors. Repeated cauterization of papillomas may according to some authors be responsible for a malignant degeneration of a benign lesion. In 30 of the 73 cases there was congenital phimosis and in 13 a long prepuce in 6 both congenital phimosis and trauma were recorded, in 10 phimosis and papilloma were present, in 2 the history mentioned trauma and in 12 no predisposing factor could be established. In regard to the location cancers of the penis may be divided into two groups (1) superficial originating from the skin or mucosa of the glans or the prepuce and (2) deep developing in the corpus cavernosum of the penis or corpus spongiosum of the urethra. As a rule cancer of the corpus cavernosum is secondary to superficial cancer. In the author's material the cancers were found most frequently in the glans the prepuce and the balanopreputal sulcus, in the order given.

From the clinical point of view the following three forms may be distinguished (1) the papillary hypertrophic form which is most frequently observed (2) epithelial ulcer or the cirrhotic form, and (3) simple infiltration of the glans.

Histologically four types of cancer may be distinguished (1) spinocellular, which is quite radio-resistant, (2) basocellular (3) mixed, and (4) transitional. The first type rapidly invades the regional glands and destroys the organ. The second type corresponds to the clinical ulcerative or infiltrating form rarely produces lymphadenopathy and shows a slow evolution. While the first type is encountered in 80 per cent of all cases the basocellular form is present only in from 0.5 to 1.0 per cent of all cases of cancer of the penis. The transitional type of cancer originates from the mucous membranes and as a rule is radiosensitive.

Sarcomas and endotheliomas of the penis are very rare. Only 1 sarcoma was encountered by the author in this group of 73 cases.

Biopsy should be done in each instance to avoid diagnostic errors. Serologic reactions are not dependable. A primary syphilitic lesion balanoposthitis ulcus molle erysipelas of the prepuce chronic cavernitis elephantiasis of the penis, tuberculosis actinomycosis syphilitic gumma papilloma granuloma venereum, and erythroplasia must be considered in the differential diagnosis.

If the lesion is confined to the glands or the prepuce, no palpable glands are present and the histologic examination establishes the diagnosis of a basocellular lesion electrocoagulation or radiotherapy may be sufficient. If the process invades the corpora cavernosa, partial or total amputation of the penis is indicated. If the scrotum is involved it may be necessary to remove it and to implant the urethra in the perineal region. If glands are involved they should be removed through an inguinoocutaneous incision.

If the testes and epididymis are affected emasculation may be required. Hormonal therapy may be tried postoperatively. If the glands are not palpable at operation the author prefers postoperative x-ray treatment to surgical removal. If the involvement is considerable, electrothermic extirpation should be followed by postoperative irradiation. If craterlike ulcerations adherent to the adjacent tissues are present in the region of the lymph glands no x-ray therapy is employed because this histologic type is usually radioresistant and because the absorption of toxic products may aggravate the condition.

If the lesion is very small well circumscribed and free of infection radium treatment is indicated. Superficial x-ray therapy from a short distance also gave excellent results in selected cases in which the lesion was small and mutilation by an operative procedure had to be avoided. X-ray therapy is also being used by the author for prophylactic purposes after electrocoagulation or extirpation of the tumor with an electric knife. Electrosurgery is always employed by the author in place of a scalpel for dissection of the tumor. JOSEPH K. NARAY, M.D.

GENITAL ORGANS

Seaman, J. A., Connelly, A. J. and Egnatz, N.: Cancer of the Prostate. *J. Urol.*, Balt., 947 57 1158.

The authors studied 100 cases of cancer of the prostate, in which 64 of the patients died and 36 remained alive for from 1 to 5 years after first being seen. Eight were subjected to castration alone, 26 were given estrogen alone, and 64 had a combination of estrogen and castration.

Most of the patients gained in weight, became more responsive, and had a decrease in anemia and an improvement in appetite. The pain was relieved the difficulty in voiding decreased, and the size of the prostate diminished remarkably in many instances. Usually it took 2 months for the improvement to be appreciable. Some of the patients received diethyl stilbestrol, 3 mgm. 3 times daily for a week and then the dose was reduced to 1 mgm. 3 times daily others received 1 mgm. 3 times a day indefinitely.

The authors re-emphasize the importance of routine rectal examinations on every male patient over 45 years of age. Additional diagnostic measures are transurethral biopsies, roentgenograms of the bones, serum acid phosphatase studies, determination of the sedimentation rate, and the Papanicolaou fixed smear technique of prostatic secretion. Scatoma in a man over 45 should be suspected as being caused by

prostatic cancer. When the diagnosis is made, complete urological examination should be done and an internist should study the pulmonary, cardiovascular and gastrointestinal systems. At present, the treatment of choice is castration plus estrogen. The problem is one of pluriglandular nature which is not yet well understood. DAVID ROSENBLUM, M.D.

Goldstein, A. E.: Extrurethral and Extravesical Perineal Prostatectomy. *J. Urol.*, Balt., 1947 57 1145.

Goldstein offers a modification of Young's perineal prostatectomy in which the adenoma is removed extraurethrally and extravesically without opening of the urethra except for the urethrotomy incision for the tractor. The dissection is made between both urinary sphincters. A retained urethral catheter is employed and a pack for coxing, and not for urinary drainage, is introduced. Where large median lobes are observed cystoscopically the operation is not attempted. The author employed the operation in 36 selected cases, and a definite decrease in mortality and morbidity rate was obtained.

For the most part the operation is the conventional perineal prostatectomy with some changes. An incision about 0.5 cm. in length is made in the upper portion of the prostatic urethra after its preliminary exposure by the conventional perineal technique. A straight Young or Lowley tractor is inserted, the blades are opened, and the prostate is drawn forward. Beginning at the upper border of the prostate on each side a longitudinal incision about 1 cm. in length is made in the prostatic capsule alongside of the urethra. The width between the two incisions is approximately 1.5 cm. The capsule is now separated from the adenoma with a blunt dissector and the index finger. Anteriorly the prostatic adenoma is separated from the anterior commissure by gently cutting the tissue between the adenoma and the anterior commissure to the bladder with a straight scissor. This also separates any anterior lobe hypertrophy that may be present. Now with the index finger behind the prostatic lobe, the instrument in the urethra is palpated. At this point a careful deliberate attempt is made to dissect the adenoma from the urethral wall. With scissors or a scalpel the adenoma which is attached to the urethral wall on each side is incised, and the lobe is gently and gradually separated medially from the urethra. This should be done carefully without tearing or pulling. Each lobe can now be delivered from the cavity. More care is taken in carrying out this procedure than in the conventional perineal prostatectomy. In separating the adenoma from the urethral wall a small opening may be made accidentally. Should this occur, no attempt is made to close it. Each lobe is removed separately.

At the completion of the removal, the prostatic cavity is examined, particularly along the urethral wall. The wall is very thin. Small tags of prostatic tissue clinging to the wall may be removed by sharp dissection. If a median lobe is present it can be removed with one of the laterals or a dissection is

made between the capsule and the urethra. The tractor is removed the internal sphincter is dilated if necessary and a soft rubber 22 F catheter is introduced. One No 1 chromic catgut suture closes the urethrotomy incision and the prostatic cavity on each side is closed similarly. For cozing a pack of gauze of oxycellulose is inserted.

Healing should be hastened because of the pressure of the urethra. In most instances the patient was allowed out of bed between the third and sixth postoperative day. Careful adjustment of the retained catheter played a very important part in the healing of the wound per primam as well as the amount of postoperative perineal urinary drainage. The catheter was kept in from 10 to 12 days. In 60 per cent of the cases the wounds were closed within 10 days and in 77 per cent they were closed within 17 days.

The average postoperative hospital stay was 22.6 days. In 5 cases there was an average incontinence of 14 days. The mortality was 2.8 per cent (1 death in 36 cases).

DAVID ROSENBLUM M.D.

Souttar H. S.: On Complete Removal of the Prostate. *Brit. M. J.* 1947 1 917

The author discusses a method of completely removing the prostate the operative approach being retropublic. The method was evolved quite by accident when he found in doing a retropublic prostatectomy that the prostate had separated from the triangular ligament. He was able to visualize the prostatic urethra which much to his surprise measured about 4 cm. The urethra was then cut close to the prostate and the prostate was then cut the bladder neck after the seminal vesicles had been divided. The bladder neck was sutured to the prostatic urethra and the bladder was further attached to the triangular ligament.

The operation which the author is now employing and which is fundamentally that described with some technical additions is discussed in detail. The article is diagrammatically illustrated which aids considerably in the clarification of the approach and the anatomical structures encountered in the retropublic space.

ROBERT LUCE, JR., M.D.

McLaughlin W. L., Holyoke, J. B. and Bowler J. P.: Oliguria following Transurethral Prostatic Resection. *J. Urol.*, Balt. 1947 58 47

The oliguria syndrome usually occurs in the so-called good risk patient, who has neither serious cardiovascular nor renal disease. The individuals who develop the type of postresection oliguria under discussion in this article appear to fall into two main groups. The first group includes the patients whose resection has been characterized by excessive bleeding and in whom a prolonged attempt has been made to control the bleeding by fulguration. Such uncontrolled bleeding is nearly always venous in origin and results from cutting through a large venous sinus in the prostatic capsule. Extensive fulguration may tend to increase the bleeding by enlarging the open

ing in the sinus. The second group includes the patients in whom an actual perforation of the vesical neck prostatic urethra or bladder wall has taken place.

Oliguria or even anuria may be present from the time of resection. In many patients, however, the decline in urinary output begins during the second and third 24 hour periods following resection. Subjectively the patient may feel entirely well but usually he complains of anorexia and nausea. Frequent hiccoughing and vomiting. Mild jaundice occasionally develops. The scanty urinary drainage is often dark brown or black. Once a state of oliguria or anuria has become established, no amount of oliguria or anuria has become established. Very occasionally a patient who has bled excessively or who has had a perforation will become uremic without showing a decrease in urinary output. The extreme dilution of the urine in these cases is further evidence of the severity of the renal damage.

Oliguria following resection is not an irreversible state. An occasional patient may have only a brief period of decreased urinary output and then go on to complete recovery. It is also true that many patients with excessive bleeding and perforation do not develop oliguria and uremia. A small percentage of the patients who have perforation go into shock and die within 48 hours. Unfortunately we have no figures on the incidence of these aspects of the problem.

JOHN A. LOEY M.D.

Murray Oscar B. and Ewert, Earl E.: Malignant Disease in the Undescended Testis. *Surg. Clin. N. America* 1947 37 709

In reviewing the literature it was definitely established that the incidence of malignant disease of the testes is markedly accelerated in testes that are undescended. In one series of 604 cases of undescended testes 11 per cent were malignant. Cancer of the testes in over 11 per cent of the recorded cases indicates a correlation 48 times greater than expected by chance association. In patients with cancer of one testis and unilateral cryptorchidism 97.5 per cent of the tumors are in the ectopic testis. In bilateral cryptorchidism with unilateral testicular cancer 97 per cent of the second testis developed in 24 per cent, whereas when both testes were in the scrotum 4 per cent of the second testis developed in but 0.7 per cent of the cases. Thus, the frequency of bilateral involvement of the ectopic testis is 32 times that of the scrotal testis.

In view of these facts the authors believe that the ectopic testes must be regarded as potentially malignant tumors and that if the unilateral ectopic testis cannot be replaced in the scrotum it should be removed.

During the last 5 years at the Lahey Clinic Boston Massachusetts there have been 50 cases of ectopic testes. During this same period 14 patients were seen with testicular tumor and in 4 of these 14 the tumor was in the undescended testis, an incidence of over 28 per cent. An average period of 15 months elapsed from the time the patient first noticed the swelling

until he presented himself for treatment. The age group was from 30 to 50 years. The Aschheim Zondek test is helpful only when positive. Diagnosis is based on a painless swelling of the scrotum.

Prien, E. L., and Fromdel, C.: Composition of Urinary Calculi. *J. Urol.* Balt. 1947 57:949.

The authors, realizing the similarity between urinary calculi and minerals have applied techniques of mineralogy to the identification of crystalline components to supplement chemical analysis which is well known to be inadequate. The use of the polarizing (petrographic) microscope and x ray diffraction techniques as applied to urinary calculus identification are described in considerable detail with a brief historical résumé.

Approximately 700 calculi were studied only 4 of which could not be identified by optical methods. This was probably due to intimately mixed foreign matter so that no other method of accurate analysis could be used but roentgenography. The great advantage of this method (x-ray diffraction) is that it affords an accurate method of analyzing calculi in respect of size contamination with organic matter, and complexity of phosphates.

Fundamentally the optical method is based on the transmission of polarized light through transparent grains the light changes then being measured and becoming constants of this particular substance. The x-ray method is one of recording the diffraction of monochromatic x rays photographically but this method is clinically impractical because of its expense and consummation of time.

The authors present detailed tables of optical constants with the appearance and association of the various substances in urinary calculi. In regard to the x ray diffraction method there are presented determinative tables and x ray diffraction photographs showing x ray spacing. The article is extremely well illustrated, presenting a very complex subject with unusual clarity. An analysis of the calculi studied is presented and their incidence computed in this series. It was found furthermore that supposed constituents of urinary calculi as reported in chemical analysis were nonexistent.

ROBERT LUCE, JR., M.D.

Suby, H. L. and Suby, R. M.: Experimental Production of Renal Calculi. *J. Urol.* Balt., 1947 57 995.

Using rabbits as test animals, the authors carried out several experiments to note the effect of the intravenous injection of urea splitting organisms on the urine pH of rabbits with normal and with hydro-nephrotic kidneys, and to obtain a favorable method of producing pyelonephritis and renal calculi in animals to simulate this disease in man.

Organisms recovered from the urine of patients suffering from calcium phosphate urinary calculi

were injected intravenously in rabbits in which an artificial hydronephrosis had been induced. The technique of producing this is described. Following the operative procedure the pH of the rabbits urine was observed for a control period of from 3 to 7 days and was found to average from 5.5 to 6.5 as measured by nitrasine paper. The animals were then given an intravenous injection of 0.35 c.c. of a saline suspension of 18 hours growth of bacteria grown from the urine of a patient with calcium phosphate kidney stones. Immediately following the injection of urea splitting organisms the urine became strongly alkaline. These urinalysis and pH determinations were followed closely and roentgenograms were taken at weekly intervals. Animals injected with bacteria which did not split urea developed a urinary infection but the urine continued to be acid. Rabbits which had normal urinary tracts when injected with urea splitting organisms voided a markedly alkaline urine for from 12 to 24 hours but the urine then again became normal and acid.

Hydronephrosis was induced in approximately 60 rabbits and various degrees of stone formation were obtained. The authors conclude from these experiments that certain bacteria after entering the urinary tract possess the power to split urea, form ammonia, and alkalize the urine this has been a common clinical observation. A similar pathological sequence was produced experimentally in rabbits. It was noted that in rabbits with normal urinary tracts, alkalization following infection is usually a transient phenomenon without resulting calculus formation. In rabbits with artificial hydronephrosis, however, infection with urea splitting organisms has produced kidney stones.

ROBERT O. BRADLEY, M.D.

Prather, G. C.: Urinary Calculi in Spinal Cord Injuries. *J. Urol.* Balt., 1947 57 997.

The author reports on a group of more than 60 patients with spinal cord injuries. Despite efforts to prevent them, calculi frequently were produced. Intravenous urograms were taken soon after admission and repeated at from 6 to 8 week intervals or more often if a febrile episode arose. Over a period averaging 13 months from the time of injury the author found an incidence of 31.5 per cent of renal calculi in patients with complete transection of the spinal cord, and an incidence of 30 per cent in those with partial transection. The higher incidence in those with complete transection is probably explained by the longer period of bed rest.

Confinement in bed and immobility resulting in stasis and hypercalciuria may be factors in the formation of calculi, yet routine urograms in bedfast patients with bladder drainage for months showed no dilatation of the kidney pelvis or ureters. When automatic voiding was established there still was no upper urinary dilatation. The authors observation in this group indicates that calculus formation is not due to anatomical change in the kidneys either during a period of prolonged bladder drainage or after some type of bladder function is re-established.

Formation of calculi occurred irrespective of suprapubic or urethral catheter drainage and irrespective of tidal or manual irrigation and during the use of solution M as the sole irrigating solution. Stones that were formed were managed as the status of each patient indicated and the results of surgery even in poor risk cases justifies an optimistic view.

ROBERT O. BEADLES, M.D.

DeVries, J. K., and Buchanan, R. W.: Absorbable Gauze in Urologic Surgery. *J. Urol.* Balt., 1947, 57: 816.

Oxidized gauze (a cellulose which has been oxidized with nitrogen dioxide) when imbedded in body tissues, is completely absorbable in variable periods of time, depending on the amount of gauze used, the amount of bleeding present, and the tissue in which it is imbedded. Photomicrographs are presented to show the gradual absorption of the gauze from experimental wounds in dog kidneys until at 4½ weeks no gauze is discernible. Fifteen weeks after packing only a narrow wedge of fibrous tissue remains where the packing was placed. The material is evidently dissolved, absorbed, and eliminated through the kidney or is taken up in solution by phagocytes.

The gauze was first tried as a carrier for thrombin, but because it is quite acid it tended to inactivate the thrombin. When the gauze is placed in contact with a bleeding surface it turns brown then black, becomes sticky and stops the bleeding. This is due to a reaction between the gauze and hemoglobin, for which it has a direct affinity. Oxidized gauze will not withstand autoclave sterilization. The product is sterilized with formaldehyde.

The authors report their experiences with the use of oxidized cellulose in 8 operations on the kidneys, 48 prostatectomies, and in 2 operations for bladder tumor.

In all instances operative wounds of the kidney were packed with the gauze, and the wounds were closed with mattress sutures, leaving the gauze in

situ. Its use was successful in controlling the bleeding in all 8 cases.

The technique used in suprapubic prostatectomy follows the standard operative approach. After enucleation of the gland a 60 c.c. Foley bag is passed through the urethra into the bladder. A square of oxidized gauze, roughly 14 cm. square, is prepared 4 to 6 ply in thickness and is secured over the bag by ties placed distally and proximal to the bag. The bag is inflated with 5 c.c. of fluid and drawn down until it fits snugly in the prostatic bed, then is inflated so that even pressure is exerted in the bed. The wound is closed with a silver wire suture extending through the abdominal wall and bladder, and secured on one side with a Davey button on the opposite side it is not secured. The bladder is then closed about a double suction suprapubic tube and the wound is closed in layers. Pressure is released from the bag in 12 hours, and urethral drainage established. The suprapubic tube is removed in 3 to 5 days, at which time the wound edges which had not been secured at the time of operation are brought tightly together and secured with a Davey button. The patient remains practically dry until the time of voiding which varies from the seventh to the fourteenth day.

It is the authors' impression that there is less bleeding with this method than with any method they have previously employed and it is also unnecessary to disturb the wound by the removal of packing. There is usually a dark red or brownish discharge from the catheter which represents disintegration of excess oxidized gauze. In one instance, cystoscopy on the sixth postoperative day showed a clean granulating wound in the prostatic bed with no evidence of gauze adhering to the wound. It is suggested that irrigation with 5 per cent sodium bicarbonate solution be instituted on the third postoperative day to dissolve the oxidized gauze.

There were no cases of secondary hemorrhage and no evidence of pyogenic reaction attributable to the oxidized gauze.

ROBERT O. BEADLES, M.D.

until he presented himself for treatment. The age group was from 30 to 50 years. The Aschheim-Zondek test is helpful only when positive. Diagnosis is based on a painless swelling of the scrotum.

The bag is inflated with 5 c.c. of fluid and drawn down until it fits snugly in the prostatic bed then is inflated so that even pressure is exerted in the bed. The wound is closed with a silver wire suture extending through the abdominal wall and bladder and secured on one side with a Davey button. On the opposite side it is not secured. The bladder is then closed about a double suction suprapubic tube and the wound is closed in layers. Pressure is released from the bag in 12 hours, and urethral drainage established. The suprapubic tube is removed in 3 to 5 days, at which time the wound edges which had not been secured at the time of operation are brought tightly together and secured with a Davey button. The patient remains practically dry until the time of voiding which varies from the seventh to the fourteenth day.

It is the authors' impression that there is less bleeding with this method than with any method they have previously employed, and it is also unnecessary to disturb the wound by the removal of packing. There is usually a dark red or brownish discharge from the catheter which represents disintegration of excess oxidized gauze. In one instance, cystoscopy on the sixth postoperative day showed a clean granulating wound in the prostatic bed with no evidence of gauze adhering to the wound. It is suggested that irrigation with 5 per cent sodium bicarbonate solution be instituted on the third postoperative day to dissolve the oxidized gauze.

There were no cases of secondary hemorrhage and no evidence of pyogenic reaction attributable to the oxidized gauze.

ROBERT O. BEADLES, M.D.

SURGERY OF THE BONES JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Mondor H., and Léger L.: Milkman's Syndrome and Spontaneous Fractures of the Skeleton (Syndrome de Milkman et fractures spontanées du squelette) *J. chir. Par.* 1947 63 85.

Röntgenological examination of bedridden patients with a diagnosis of chronic rheumatism or hysteria will often reveal multiple symmetrical fissures of the bones. These narrow radiolucent lines may be seen in the long bones, pelvis, or ribs, but there is never any evidence to correlate these x-ray findings with trauma. Furthermore, the site of the pain has no bearing on the location of the fissures. In fact, they are often discovered in bones which apparently are asymptomatic. Therefore it is necessary to roentgenograph the entire skeleton in the search for these bony lesions.

Patients localize the pain predominantly in the spine, pelvis, and lower extremities. It is initiated by any physical effort i. e. change of position or by a brisk walk. There is general weakness and the patients very cautiously carry out very simple tasks such as lifting a spoon or turning a page. Some patients become totally helpless. The gait is insecure and often waddling. There are often skeletal deformities, unassociated however with the bony fissures. Kyphoscoliosis of the spine is most frequently seen. One patient seemed to have shrunk 13 cm. in height.

There were no typical laboratory findings. The blood calcium was normal in most patients (elevated in 8 patients) and the blood phosphorus varied from 16 to 103 mgm. per liter. Cholesterol, blood sugar, the albumin-globulin ratio, acidity of the urine and urine phosphorus excretion did not show any significant changes. The serum phosphatase was elevated as a rule, the values ranging up to 48 Bodansky units. The basal metabolic rate was found to be elevated in 6 cases (plus 5 to plus 41 per 100). The Wassermann reactions were negative except in 1 patient afflicted with tabes. Surgical exploration of the parathyroids was negative (Milkman).

In view of the negative laboratory and clinical findings the condition is often diagnosed as hysteria. The roentgenograms later indicate organic changes in the skeleton which often are diagnosed as osteomalacia, multiple myeloma, or polyneuritis.

Milkman's syndrome has a number of signs in common with chronic rheumatism, for example, the patient's age, absence of infection, imperceptible yet continuous progression of the disease, limp, limitation of motion, and often bilateral symmetrical affections of the joints. The following signs help to make the diagnosis of Milkman's disease: general ill health and extreme weakness with a lack of clinical findings, apparent obesity, a peculiar gait, severe

pain, rapid progression of the disease, and firm contractions of the abductor muscles of the hip with limitation of motion in the hip joints. The femoral heads become mis-shaped and the articular space thinned, and periarticular calcifications are often found.

The fissure lines in bone are not true fracture lines in the sense that they have not been caused by an injury; there is no displacement of the fragments, and there is no pain on pressure over the area. These fissures are the result of local changes associated with local decalcification but without interruption of the continuity of the bone. The bony fissures are surrounded by an area of radiolucency and represent "Umhauungen." The area of translucency is about 3 or 3 mm. wide (Resorptionssäume of Kienboeck) and is perpendicular to the long axis of the bone. The neighboring bony tissues do not show any changes except occasionally a slight change in the trabecular pattern. The periosteum is elevated and forms a sleeve around the fissure such as is often observed around a fracture site where the callus unites two bony fragments. The most important characteristic feature of this disease is the multiplicity of these fissures (from about 8 to 43 fissures seen in 1 patient). The symmetry of the lesions often is remarkable. Every bone may be affected except the skull. In all the patients examined by the authors 110 fissures were seen in the pelvis, (of which 61 were seen in the ischopubic bones) 42 in the femur, 40 in the ulna, 21 in the scapula, 19 in the ribs and 18 in the fibula.

Under the influence of "mechanical factors," lamellar bone is replaced by reticular bone and the fissure appears. It is the authors' opinion that at one given moment a fracture must be present in spite of the absence of subjective symptoms.

Histologic examination of these lesions in the femur showed local bony changes resembling osteoporosis, while examination of the lesions in the fibula suggested osteomalacia. The cortex and the periosteum appeared to be thickened at the site of the lesion (Michaelis). In 1 case a complete autopsy examination was done (Milkman). Many diffuse lesions of the cerebral arteries were found, and hemorrhage in the thalamic region, kidneys, ovaries, and suprarenals. Hyaline degeneration of the walls of vessels was also observed.

Roger and Huguet examined a number of roentgenograms of patients affected with Milkman's syndrome and concluded that the condition was skeletal carcinoma metastases in spite of the fact that the primary tumor could not be localized. The differential diagnosis of Milkman's syndrome often offers a great deal of difficulty. Syphilis of the bone often causes fissures in the bones (Balc, Alexander). Observations similar to those referred to Milkman's disease were made by Kienboeck in osteogenesis

imperfecta and by Merle d Aubigny in intrauterine fractures. Similar fissures were observed in von Recklinghausen's osteitis fibrosa. Tiller suggested that there are intermediary stages between true rickets and Milkman's disease.

Osteomalacia and Milkman's syndrome have features a great deal in common, i. e. predominance in females, diffuse bony pain, progressive course, general ill health and similar therapeutic response. General decalcification of the skeleton is less marked in Milkman's disease. Although skeletal deformities like curvatures of the spine due to collapsed vertebrae and coxa vara are also observed in Milkman's syndrome, they do not form part of the disease entity. Hypocalcemia with normal blood phosphorus, so characteristic for osteomalacia is absent in Milkman's disease.

Rechad Balger compared Milkman's disease with osteopathia due to dietary deficiencies ("Hunger Knochenerkrankung Hunger Osteomalazie"). These 2 conditions have a number of findings in common and many workers indeed feel that they are analogous. The fact has to be mentioned however, that dietary deficiency cannot account for all the signs found in Milkman's disease. Histologic examination of the bony lesions of famine osteopathia showed thinning of the cancellous and compact portions of the bone. Osteoid borders surround marrow cavities filled with an embryonic type of mesenchymal tissue.

March fractures are differentiated by their location and etiology. They have been observed frequently in patients with dietary deficiency rickets and osteomalacia.

Bone grafting procedures and for that matter, any type of surgical intervention is contraindicated in Milkman's syndrome. They were tried in several instances and the fragments remained separated for 4 years and 9 months after the bone grafting procedure. Administration of vitamin D and tricalcium phosphate caused consolidation of the graft and disappearance of pain within a month. Arsenic preparations in combination with phosphorus were used in 1 case with improvement after a few months and cure after 4 years.

Calcium and vitamins are used by most authors. The use of parathyroid extract seems to be contraindicated since it tends to mobilize calcium from the bones into the blood stream. In cases in which metastases are suspected castration by deep x ray therapy is indicated.

The histories, physical examinations, laboratory findings, and roentgenograms of 8 patients are described in great detail. GEORGE I. REISS, M.D.

Sherman, Mary S.: Osteoid Osteoma Associated with Changes in the Adjacent Joint. Report of 2 Cases. J Bone Surg. 1947 29 483.

The article consists of a brief discussion of osteoid osteoma associated with adjacent intra articular changes, and 2 case reports.

The disease is characterized by night pain which may be fleeting or constant, and tenderness and

swelling at the lesion area with joint effusion. The presence of systemic manifestations such as temperature elevation and leucocytosis excludes osteoid osteoma. The roentgenograms may be normal in the early stages of the disease, but they are quite characteristic when the lesion is fully developed. The main portion of the eccentric lesion is radiolucent. The periphery may be marked by a ring of dense bone. The regional bone about the osteoid osteoma may be markedly hypertrophied. It is of interest to note that the lesions fail to grow larger over a period of years, but tend to become increasingly painful and disabling. The treatment of choice is surgical extirpation. In no case has there been any local recurrence.

Microscopically the lesion consists of vascular fibrous tissue with giant cells, osteoblasts and osteoclasts. Its stroma may be diffused with an irregular Paget like pattern of trabeculae which exhibit unequivocal properties of osteoid tissue.

Two cases of 33 osteoid osteomas observed at the University of Chicago disclosed a concomitant hypertrophic arthritis. These cases form the basis of this report.

Case 1 was that of a 16 year old girl who had hip symptoms for 2 years. Pain limitation of motion, and loss of 25 pounds of weight were the chief features. Upon roentgenologic examination of her right hip two oval areas of decreased density were noted on the medial aspect of the neck of the femur. Operation revealed marked villous proliferation of the synovial membrane and about 100 c.c. of clear xanthochromic fluid. Marginal osteophytes were also noted on the head of the femur. Bone chips removed from the neck of the femur had the appearance of osteoid tissue.

Case 2 was that of a boy aged 13 suffering from pain in the left elbow swelling and limitation of motion. An increased sedimentation rate of from 25 to 38 mm per hour was noted. His symptoms had been present 3 months when he was first seen. Examination of the aspirated joint fluid and guinea pig inoculation were negative.

A roentgenogram of the elbow showed a slight thickening of the lower end of the humerus, with an irregularity of the ossification center of the trochlea. Conservative treatment did not affect the progress of the disease. Nine months after the onset of the condition the x rays disclosed a round radiolucent mottled bone defect occupying the olecranon fossa. The lower end of the humerus was markedly thickened by reactive bone formation and appeared to have lost its anatomical configuration.

Since penicillin and sulfonamide therapy failed to change the clinical course the elbow was explored. Tissue studies disclosed microscopic changes similar to those noted in the previous case report, i.e. osteoid osteoma.

Final appraisal of both cases seems to indicate that the acute joint symptoms promptly abated following the surgical removal of the osteoid osteoma, and to date they have not returned.

SAMUEL L. GOVERNALL, M.D.

Kristensen, Gerd Schwartx, and Wulff, Ferd.: On the Course of Paralytic in Polymyellitic Patients. *Acta med. scand.*, 1947 187: 361

The authors analyze their study of a large number of patients severely paralyzed by polymyellitis.

The 5 muscle grades employed in Scandinavia appear to correspond with those used in the United States, although the exact description of them differs slightly. The analysis is based entirely on clinical data and depends upon the record of repeated muscle tests at varying intervals.

The authors assume that if a severely affected muscle shows no substantial improvement in 3½ months, but nevertheless regains almost full strength in time, this improvement is due largely to regeneration of the conduction system. Improvement after about a year is said to be due to the working up of muscular strength by exercises.

The treatment of all the cases consisted of exercises and training. In very badly paralyzed muscles electrical stimulation was used to keep them in form until they were receptive to active therapy. The Kenny treatment was not used.

Three groups of cases are included in the following summaries:

- 1 Those examined at the beginning of the disease and again in 9 months.
- 2 Those examined at 3½ months and again at 9 months.
- 3 Those examined at 9 months and again in 4 to 8 years.

Of those with muscular power at 0 at the beginning of the investigation, only about 6 per cent of those in the first group can be expected to improve to IV plus V about one half to V, and only about 1 to 3 per cent in the second group can be expected to reach IV plus V. None in group 3 can be expected to reach IV plus V.

Of those with muscular power at I at the beginning of the investigation, about ¾ in the first group can be expected to improve to IV plus V (about one half to V) in group 2 the chance of improvement falls sharply—less than 10 per cent can reach IV plus V. None in group 3 can be expected to reach IV plus V.

Of those with muscular power at II at the beginning of the investigation, about ¾ in group 1 can be expected to reach IV plus V (about ¾ reaching V), about ¾ in group 2 can be expected to reach IV plus V (about ¾ reaching V) and about ¾ in group 3 can be expected to reach IV plus V (about ¾ reaching V).

Of those with muscular power at III at the beginning of the investigation, about 90 per cent in group 1 can be expected to reach IV plus V (about ¾ reaching V), about 75 per cent in group 2 can be expected to reach IV plus V (about ¾ reaching V) and about 60 per cent in group 3 can be expected to reach IV plus V (about ¾ reaching V).

Of those with muscular power at IV at the beginning of the investigation, about 90 per cent in group 1, about 80 per cent in group 2, and about 65 per cent in group 3 can be expected to reach V.

The muscular power is classified as follows: Grade 0 = no contraction, I = palpable contraction, II = deflectional movement against neutralized gravitational pull, III = deflection against gravitation or against slight resistance, IV = deflection against greater resistance, and V = full or almost full strength. IV plus V denotes function useful for the performance of work.

Moeborg, Erik: Subcutaneous Rupture of the Tendon of the Tibialis Anterior Muscia. *Acta chir scand.*, 1947 95: 455

Four case histories which have been presented previously are briefly reviewed. The author has observed an additional 4 cases.

In 2 of the author's cases the history and physical examinations are presented in detail and in these cases no operative interference was carried out. In 1 of these cases, 3 years have elapsed and the patient can walk and run normally. In the second nonoperative case, the end result is not noted.

In the author's third case, an operation was performed and good function was obtained, but the range of movement and muscular power in dorsiflexion is still reduced. In the author's fourth case, the ruptured tendon was sutured and the function of the foot was completely restored. The patient returned to work in 14 weeks.

The author brings out the fact that all of the known cases have occurred in men. These ruptures of the tibialis anterior tendon are localized to the passage under the crucial ligament. Upon examination immediately after the injury when the patient tries to tense the tendon the distinctly visible and easily palpable outline of the tendon is not present. The local symptoms are not very marked and are usually transient. The ability to walk is not lost. Even local hemorrhage and swelling are often minimal. The foot cannot be handled properly and may droop. If this condition is not treated surgically some restriction of movement, reduced strength, and secondary pes planus may be the ultimate result. A suture of the tendon is desirable unless surgical interference is contraindicated. The author suggests a method of repairing the ruptured tibialis anterior tendon when the gap between the torn ends is considerable. Undoubtedly rupture takes place only when there are pathologic changes in this tendon.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Haggart, G. E.: The Treatment of Primary Malignant Bone Tumors of the Humerus. *Surg. Clin. N. America*, 1947 27: 77

In suspected malignancy of the humerus the author advises biopsy if the diagnosis is much in doubt but relies on a frozen section study to confirm the diagnosis if the clinical and roentgenological features strongly indicate malignancy. He treats these lesions, when they are operable, by interscapulo-

Group 3 comprises 13 patients, as follows.

(a) Nine patients who have remained in remission during the administration of small doses of 0.1 to 0.2 gm. daily, but who relapsed when the drug was withdrawn. Of these 1 was a male and 8 were females; the majority were less than 40 years of age. The average duration of thiouracil administration was 1 year and the longest 19.5 months. Three of the patients developed moderately severe signs of edema and congestion of the lids and conjunctiva, and 2 exophthalmos.

(b) Two patients who relapsed when the dose was reduced to 0.2 gm. both of whom had nodular goiter.

(c) Two patients were maintained on small doses, without relapse. The first patient was a woman, aged 69, with nodular goiter, diabetes mellitus, moderate hypertension, congestive heart failure, and a basal metabolic rate of plus 46 per cent. Thyroidectomy was performed at the end of 11 months because of pressure symptoms. The second patient was a man, aged 22, with an initial basal metabolic rate of plus 59 per cent and a diffuse goiter. His goiter decreased in size over a period of 8 months.

Ten of the 13 patients in group 3 were in the third and fourth decades of life, and 3 were in the sixth decade. Eight had diffuse goiter, 3 nodular and 3 recurrent postoperative goiter.

Group 3 comprises 6 patients (1 male and 5 females) who failed to show satisfactory response over periods of 7 to 15 months. Five patients were above 44 years of age; 4 had a complicating disease, such as acromegaly, hypertension, myocardial enlargement, diabetes, epilepsy, and auricular fibrillation.

Five of the 35 patients in the present series exhibited a leucopenia of less than 4,000 white cells per cubic millimeter. One of these, following a period of abstinence, exhibited no recurrence of leucopenia when the drug was readministered. One had leucopenia several months after cessation of therapy; this was thought to be due to the hyperthyroidism rather than the therapy. One patient had a severe granulocytic pharyngitis, and fever. One developed maculopapular dermatosis.

CLETON H. THURMOND, M.D.

Lahey F. H.: Surgery of the Thyroid Gland. *N. England J. M.*, 1947 236 46.

The author's review is based on his experience with between 35,000 and 36,000 operations on 22,000 to 23,000 patients with thyroid disease, during a period of 30 years. The operative mortality was 0.73 per cent and the patient mortality 0.88 per cent. Thiouracil, thiobarbital, and propylthiouracil have been used preoperatively in a recent series of 500 cases, with a patient mortality of only 0.17 per cent. The author believes that these drugs interfere with the elaboration of thyroxine by the thyroid gland but states that the action of administered thyroxine is not altered. At operation, however, the gland is very friable and microscopically has the typical appearance of a toxic, hyperplastic gland, unless iodine is given the last 3 weeks before surgery when the hyperplasia regresses.

At the Lahey clinic, Boston, it is now the practice to discontinue thiouracil 1 week before surgery, to

avoid the possibility of agranulocytosis at the time of surgery. The average stay in the hospital before the thiouracil era (with iodine treatment preoperatively), was 55 days for the 3 stage operation, and 35 days with the two stage operation. With thiouracil and iodine the average stay is 8 days.

Complications due to these drugs are as follows: neutropenia, granulocytopenia, fever, skin eruptions, and enlargement of the salivary glands. These occur in 9 per cent of patients receiving thiouracil and in 28 per cent of those treated with thiobarbital. Experience with propylthiouracil included 60 patients submitted to surgery and 100 in preparation, with 2 showing leucopenia. When these complications occur and the drug is withdrawn until disappearance of the complication, readministration of the drug is associated with a greater hazard of recurrence. Agranulocytosis and neutropenia occurred as late as 8 days after the last dose of thiouracil, and as late as 9 months after beginning administration on as low a daily dose as 0.2 gm. Agranulocytosis is treated with penicillin, pyridoxine, and liver extract with the greatest dependence on penicillin.

Apathetic hyperthyroidism is described as a chronic, low grade hyperthyroidism in older people, usually with only a small increase in basal metabolic rate with myasthenia and loss of weight. Subtotal thyroidectomy results in recovery.

The importance of subtotal thyroidectomy in thyrocardiac disease is emphasized.

Other phases of hyperthyroidism discussed are myasthenia, exophthalmos, diminished liver function, cancer of the thyroid, variations in relations of recurrent laryngeal nerve, intrathoracic goiter, and the use of lipocac in the control of diarrhea associated with hyperthyroidism. CLETON H. THURMOND, M.D.

Fig. 1 F. A.: The Etiology and Treatment of Cicatricial Stenosis of the Larynx and Trachea. *Semin. M. J.*, 1947 40 17

In a group of 42 cases of cicatricial stenosis of the larynx and trachea, fracture of the cartilages and previous removal of tumors were the most common causes of stenosis. Other less frequent causes were acute infections self-inflicted and accidental severing of the trachea, and the use of nasal feeding tubes.

The stenosis was treated by an open operation, that is by thyrotomy, excision of the scarring, and skin grafting in 27 cases by continuous dilatation with or without incision of the scar in 10 cases, and by repeated incision of the cicatricial diaphragm in 2 cases. The treatment is described in detail.

Prolonged dilatation was carried out in all the cases after skin grafting.

In 24 of the 27 patients treated by skin grafting the lumen is ample, and in 23 patients the tracheotomy opening has been closed. In 3 of the 10 patients who were treated by continuous dilatation decannulation has been carried out. Both of the patients who were treated by repeated incision of a cicatricial diaphragm have, at the time of this report, a free air way.

Fig. 1 (Hagart) Completion of posterior muscle dissection. Clavicle has been cut and arm allowed to fall forward; this clearly delineates the brachial plexus and subclavian vessels.

Fig. 2 (Hagart) With exception of the latissimus dorsi all the anterior muscles have been divided. At operation the cut ends of the plexus and subclavian vessels are completely covered by the proximal flap.

thoracic amputation. Not only has the operation prolonged life in patients without demonstrable metastases, but it has prevented continued extreme suffering when employed simply as a palliative treatment.

The operative technique of Littlewood is preferred to that of Berger. This method does not require the surgeon to work in a deep hole and the subclavian vessels and brachial plexus can be identified and treated relatively simply.

Five cases are presented to show the worthwhile results of this operation. The operative technique is presented with good illustrations.

NEWTON C. MEAD, M.D.

Mellen Richard H.; and Phalen George S.: Arthroplasty of the Elbow by Replacement of the Distal Portion of the Humerus with an Acrylic Prosthesis. *J Bone Surg.*, 1947 29 348.

The authors present 4 cases in which an acrylic prosthesis replaced the distal portion of the humerus.

In the first case it was believed that an acrylic type of prosthesis might be used on the humerus to provide a fulcrum for the elbow joint and still allow early motion in the elbow, thus avoiding the long period of time which would be necessary for healing if a bone

graft were used to prolong the humerus. The procedure was carried out with gratifying results.

A similar problem presented itself in several cases of nonunion in the supracondylar region of the humerus. In these cases 3 of which are reported the distal fragment of the humerus was malunited and the elbow joint was fixed by fibrous ankylosis. This mitigated against the restoration of any satisfactory painless motion in the elbow itself after bone grafting of the humerus either alone or in combination with a conventional arthroplasty or resection. It appeared likely that the entire ununited distal fragment of the humerus might well be replaced with a functional type of plastic prosthesis, thus restoring the fundamental principles of the hinged type of joint inasmuch as the proximal portion of the ulna was undamaged and could furnish a satisfactory point of rotation.

The prostheses were made of veronite, a methyl and ethyl methacrylate. This material was cast in the form of models which were fashioned after the authors' idea of a functional form for the distal portion of the humerus and did not attempt to duplicate the normal anatomy of the bone. The central hole of the prosthesis was drilled out on a lathe. The size of the central cavity was approximated for each case by

a preoperative measurement of the roentgenograms of the distal shaft of the humerus over which the prosthesis was to fit. At the elbow a standard operative approach was used usually modified by the type of injury and the presence of previous scars or skin grafts. The prosthesis was secured to the distal portion of the humerus either by tantalum wire or vitalium screws; these were placed through holes in the prosthesis which were easily drilled at the time of operation after the prosthesis had been fitted snugly over the end of the humeral shaft.

Three of the patients described have been followed for periods ranging from 9 to 18 months since the operation. Several striking things have been noted. Immediately after subsidence of the postoperative reaction, motion was restored to the maximum amount obtained, and, as weeks went by, strength in the flexor and extensor muscles improved, but very little improvement in range of motion occurred. This was probably due to the fact that from the start, very little pain was present on motion and at the last evaluation the patients complained of no pain whatever. Furthermore the elbows were comparatively stable.

Inasmuch as the distal end of the humerus is enclosed in this more or less impervious acrylic cap, the fate of this portion of the bone in regard to nutrition and future atrophy is uncertain and will have to be determined by a longer period of observation. The purpose of this report is to stimulate interest in a simple type of procedure which apparently restores motion to the elbow quickly and relatively painlessly. The authors believe that this procedure might possibly be of benefit in ankylosed elbows resulting from rheumatoid arthritis. RUDOLPH S. RABIN, M.D.

Mahoney James H., Phalen, George S., and Frackelton, William H.: Amputation of the Index Ray. *Surgery* 94:7 31 9 1

The index finger ranks second only to the thumb in importance and because of this, surgeons have been taught to salvage as much of this finger as possible when treating an injury affecting it. However in treating a large number of cases on a hand service at an Army general hospital, the authors found that such salvage often resulted in the loss of efficiency in the use of the hand, this being true especially when the index finger was amputated at a point proximal to the proximal interphalangeal joint. In these cases an amputation of the index ray (index finger together with the second metacarpal bone) resulted in the restoration of almost normal function of the injured hand.

Amputation of the index ray is recommended only in patients with normal or nearly normal function of the remaining digits of the hand. These cases fall into two groups: (1) patients with the index finger amputated proximal to the proximal interphalangeal joint, and (2) patients with the index finger so badly damaged that any reconstructive surgery would hold little promise of restoring fairly normal function of the digit.

Time and money are factors which must be considered in deciding whether a finger should be amputated or reconstructed. Instead of spending from 6 to 18 months in a futile attempt to restore the index finger to normal, the patient might find it to his advantage to submit to an amputation of the index ray and return to work within 18 days.

During the past year 18 amputations of the index ray were performed. In every case the dexterity of the hand was improved and the patient expressed satisfaction with the end result. While restoration of an efficiently functioning hand is of primary concern, it is a happy coincidence that the cosmetic appearance of the hand is also improved.

In performing an index ray amputation an incision is made about the base of the index finger extending longitudinally on the dorsum of the hand to the base of the second metacarpal. The second metacarpal is exposed subperiosteally and osteotomized just distal to its base. The base of this bone is not removed because it is desirable to preserve the insertion of the extensor carpi radialis longus tendon. If possible the tendon of the first dorsal interosseous muscle is isolated and inserted into the tendon of the second dorsal interosseous muscle. This tendon transfer increases the power of the long finger to resist pressure from the thumb. The digital nerves are carefully isolated, ligated and buried to prevent the formation of painful neuromas. Through a small separate transverse incision at the wrist, the flexor tendons of the index finger may be withdrawn and transferred into the flexor tendons of the long finger.

Amputation of the index ray narrows the breadth of the palm and this may not be too desirable in a patient who must perform heavy manual labor. However the increased dexterity obtained more than compensates for the slight diminution in breadth of the palm. RUDOLPH S. RABIN, M.D.

FRACTURES AND DISLOCATIONS

Carlquist, Nils: Comparison of the Results from Nonoperative Treatment and from Osteosynthesis by Multiple Nailing of Medial Fractures of the Collum Femoris. *Acta chir scand* 94:7 95 Supp. 187

A survey of the vast literature on medial fracture of the neck of the femur is presented as a background for this study. Until 1939 in the Surgical Clinic of the Lund Hospital all medial neck fractures were treated nonoperatively. Beginning in 1940, the multiple nailing technique of Nyström has been used consistently and a follow-up system has made it possible to investigate the progress of the patients so treated. The author presents a comparative study of the nonoperative cases treated between 1930 and 1939 and the cases treated by the multiple nailing method of Nyström between 1941 and 1945. The studies investigated especially the healing of the fracture and its most common complication—necrosis of the femoral head—under the different methods of treatment.

The material from 1920 to 1939 included 473 patients with fresh medial neck fractures. Active treatment, i.e. reposition under ether anesthesia followed by either plaster cast fixation or skeletal traction, was employed in 73.7 per cent of the group. The primary mortality was 15.6 per cent the chief causes being thromboembolism and pneumonia. Complications consisted primarily of these two conditions plus decubitus. Of this group 73 patients have been re-examined clinically and roentgenographically. Bony union was demonstrated in 72.6 per cent of these cases.

An exhaustive analysis is made of all factors which might contribute to healing both those independent of treatment (age, sex, weight, type of fracture, and degree of displacement) and those dependent on the treatment (interval before active treatment was instituted, character and effectiveness of the fixation, duration of nonweight bearing, duration of total treatment). The only statistically justifiable conclusion derived from this painstaking analysis was that the character and effectiveness of fixation are of paramount importance in securing healing.

Capital necrosis in the healed cases occurred in 24.6 per cent but no tenable contributory factors could be established.

From 1940 to 1945 there were 259 cases of fresh neck fractures admitted of which 161 were treated by multiple osteosynthesis according to Nyström. This briefly consists of nailing with 3 relatively small triangular nails, under local anesthesia followed by 7 or 8 weeks of bed rest during which daily massage and active joint motion are carried out. The primary mortality was 7.3 per cent from the same causes as in group I but these cases occurred during the era of chemotherapy. The operative technique and the early and late complications following treatment are discussed succinctly. The incidence of decubitus was strikingly low in comparison with that in the earlier series.

Of the 134 patients living at the time of this study 128 were re-examined clinically and roentgenographically and only the 83 cases which had been followed up for at least 2 years were included in the results. Bony healing was present in 88 per cent, but 16 of these cases showed only partial osseous healing with capital necrosis in 81.3 per cent of them. In the cases of complete healing there was an incidence of 24.6 per cent of capital necrosis. All of the factors studied in the first group were studied in relation to healing and the occurrence of capital necrosis in this series. Slipping of nails or perforation into the joint were found more often in cases of capital necrosis presumably due to the changes in the character of the head. In 41 per cent of the 83 cases capital necrosis occurred and it was most frequent in the patients who were reoperated upon. Reoperation was usually done because of slipping or perforating nails in the changed femoral heads.

That the two groups of cases are comparable statistically is developed in a detailed study of the age groups and percental distribution.

Initial mortality was halved in the operative group in which not only the availability of chemotherapy, but undoubtedly the early mobilization in bed and earlier getting up play important roles. The mortality after discharge from the hospital was also halved in the operative patients presumably because of the reduced strain of the briefer operative regime on old patients. Less discomfort to the patient, reduction of demand on nursing personnel and shortening of the hospitalization period by an average of 1 month are points in favor of the operative treatment. The higher frequency of healing in the osteosynthesized group was ascertained also the ability of this method to give better fixation and less neck absorption than the nonoperative treatment. Occurrence of capital necrosis showed no significant difference in the 2 methods, ascribable to the fact that probably damage at the time of fracture rather than the type of treatment determine its onset. Clinical results are strikingly in favor of the nailed cases although the fact that the period of observation for these cases is relatively short (2 years or more) is given proper consideration. These findings quite definitely indicate that osteosynthesis is the superior method of treatment in the cases of medial neck fracture.

ORTHOPEDICS IN GENERAL

Abbott LeRoy C. Schottstaedt, Edwin R. Saunders, John B. deC. M. and Boast, Frederic C.: The Evaluation of Cortical and Cancellous Bone as Grafting Material. A Clinical and Experimental Study. *J. Bone Surg.* 1947, 29, 381.

The purpose of this excellent presentation is to evaluate the relative applicability of cancellous and cortical bone as a grafting material. The findings are based upon experimental work, microscopic studies of human grafts and clinical data. Rabbits and dogs were used as follows:

Variable lengths of cortical tibiae from 0.8 to 2.8 cm. long and full thickness bone were used in the first series of 52 animals. The grafts were as follows: 7 of cancellous bone, 5 of cortical bone and periosteum, 8 of cortical bone without periosteum and 12 of cortical and cancellous bone. There were 10 controls, respectively. It was learned that there was very little difference whether the periosteum was intact or not. At the end of 10 days the cortical bone showed evidence of degeneration. Haversian systems were invaded by granulation tissue and creeping substitution ensued throughout the graft. Observations of the cancellous graft, however, disclosed earlier revascularization with moderate disintegration of the trabeculae.

In the second series complete resection of a segment of the middle of the shaft of the radial bone was done, and the defects were filled with grafts from the cancellous portion of the ilium, rib or the cortex of the tibia. Of the initial 64 animals only 35 were acceptable for study. The grafts were as follows: 11 of cancellous bone, 8 of cortical bone and periosteum.

and 6 of bone from the rib there were 7 controls. The authors' conclusions regarding this group were similar to those regarding the previous series.

In the third series excision of the knee joint was performed with supplementary grafts of cortical and cancellous bone. Of 45 dogs 32 were used for the study. Under aseptic technique all knee joints were exposed. The patellae, and the femoral and tibial cartilage were removed. The extremities were immobilized with 2 or 3 Kirchner wires and plaster of Paris casts. The types of grafts were as follows: 16 of cancellous bone, 10 of cortical bone from the tibia with periosteum, 14 of cortical bone without periosteum. There were 18 controls. On the whole the results obtained in this series compared favorably with those of the first two—that is, when cancellous and cortical grafts were used. Experiments in the present series convinced the investigators that cancellous bone is, by far, the most exuberant grafting material which can be used in and about joints. The rapid revascularization of trabeculae by vascular granulation places cancellous bone at the top of the list. Other advantages are: (1) earlier growth of many more osteoblastic cells, and (2) rapid incorporation of the graft with union to the host, and early trabecular deposits of collagen which are lined by osteoblasts.

In the fourth series iliac bone, cortical bone, and bone from the spinous process or the rib was placed in split spinous processes. Eight dogs were used for this experiment. Fifty-four grafts were secured from 6 animals. The ultimate behavior of the cancellous and cortical bone was similar to that observed in previous experiments. However, when the split thickness rib graft and the split spinous process grafts were utilized, it was noted that their respective medullary surfaces were promptly invaded by vascular granulation tissue. Creeping substitution over dead trabeculae occurred more rapidly. This diphasic osteoblastic phenomenon contributed largely to an early bone formation, similar to cancellous bone but in contradistinction to cortical bone.

In the fifth series 7 dogs were used. A portion of the tibia was excised. Cancellous transplants were used in a cancellous bed. Iliac bone was the source of the grafting material. In one group of 16 secured specimens, the grafts were not well immobilized.

Sudden death of the bone ensued. This was due to long contact between the grafts and the host. Moreover, when grafts were accurately approximated and immobilization was established, bone union developed rapidly.

The results of the experiments seem to indicate that revascularization of a cancellous graft must of necessity occur within the first 10 or 15 days. Beyond that period survival may be in jeopardy. Specimens of iliac bone at 31, 42, and 60 days, respectively, showed insidious, yet progressive, restoration of the trabeculae. Changes in the rib grafts were comparable to those of the cortical and cancellous bone of the tibia, except that the vascular granulation was more prodigious and bone formation equally rapid in the rib. Too rib grafts exhibited a quicker and better attachment to the host. It is also of interest to note that in split rib grafts, revascularization occurs more rapidly than in whole ones. Split spinous process grafts reacted like split rib grafts.

In the summary the authors state that fully matured bone, be it compact or cancellous, behaves the same in nearly all cases. Once such bone is transplanted, for the most part it does not survive. It is inevitably replaced by creeping substitution. The osteogenic power of any graft is found only in the endosteal layer. The rest of the bone is inert. The same can be said of the cambium layer of the periosteum. When a cortical graft receives an inadequate blood supply via its haversian system, failure to survive results. Hence, its main function is one of internal splinting. In the case of cancellous bone, with the many endosteal trabeculae exposed to a richer blood supply and greater osteogenic power, bone formation ensues quite rapidly.

Fat has proved to be an inhibitory element when present in excessive degree in the cancellous grafts. It is well known that it retards bone formation. Cortical bone as a grafting material is most efficacious where strength is of paramount importance. The endosteal layer affords an excellent combination for defects or nonunion of the long bones. For the obliteration of cavities, cancellous bone is recommended. Cortical grafts seldom survive infection. Their ultimate fate is sequestration.

SAMUEL L. GOWERKALE, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Coller Frederick A.; Campbell, Kenneth N.
Berry Robert E. L. Suttler Martin R. and
Others: Tetraethylammonium as an Adjunct
in the Treatment of Peripheral Vascular Dis-
eases and Other Painful States. *Ann Surg.*
1947 125 729

The authors report clinical observations of a large series of patients with peripheral vascular disease who received one or more injections of tetraethylammonium to produce autonomic blockade. Ache ethylammonium ion would block transmission of nerve impulses through autonomic ganglia. The pharmacology is briefly discussed.

The administrations were carried out with the patients placed in a recumbent position and the extremities uncovered the temperature of the room was kept constant (68-75°) and thermocouple record bromide) in a 10 per cent solution was slowly injected. The intravenous doses were slowly in- 500 mgm. Intramuscular doses were also given.

The first group of cases reported consisted of patients with a diagnosis of causalgia. Briefly the basis for the authors' diagnosis consisted of a history of some or all of the following: (1) previous trauma sometimes almost insignificant, (2) abnormal or disproportionate prolongation of pain, usually directed peripherally to the hand or foot, (3) the occurrence of vasomotor phenomena over a time interval disproportionate to the initial trauma, (4) a frequent affection of the morale of the sufferer, (5) frequent roentgenographic demonstration of early cystic or late diffuse osteoporosis in the involved extremity, (6) cessation of pain and/or amelioration of the clinical picture following blocking or extirpation of the sympathetic ganglia supplying the involved areas. Twenty cases are reported in detail. The authors conclude that the use of tetraethylammonium produced satisfactory results in certain patients in whom not believed to be feasible because of the presence of a psychogenic element or an unstable personality.

Nine patients with herpes zoster and postherpetic neuralgia were treated. All received some relief varying from a brief period to 6 hours. The role of vasospasm and the mode of relief could not be explained.

The third group consisted of patients with functional vascular disease. Because the effects of the drug are transient they were of little therapeutic value. In this group and particularly in patients with Raynaud's phenomena, attacks could be aborted or modified but the drug did not replace sympathetic

Thirty five patients with thromboangiitis obliterans were studied. The authors thought that the re-

sponses to the injections of the drug could be utilized to gauge the degree of occlusion and collateral arterial circulation and to predict the response of the involved extremities to appropriate sympathectomy. The drug afforded relief of pain in many instances, particularly rest pain and the injection was followed by visible palpable, and measurable relief of vasospasm when clinically present. It was thought that the drug was of no avail in the presence of severe infection or established gangrene. One patient with severe intractable pain was reported to have obtained remarkable relief and to have been converted to a pain-free ambulatory patient.

One hundred and twenty-five patients with peripheral arteriosclerosis obliterans received tetraethylammonium as a diagnostic, prognostic or therapeutic measure. The drug was useful in this group in two respects: (1) it aided in the control of nocturnal pain and (2) it was an index of possible benefits that might be derived from lumbar sympathectomy. Only the occasional arteriosclerotic shows improvement in claudication and established gangrene is not modified.

Twenty-six patients with thrombophlebitis were treated. The pain and edema of acute and subacute cases responded excellently. Patients with chronic thrombophlebitis noted subsidence of the edema relief from congestive pain, and a new sense of well being. The benefits were in no sense curative but provided satisfactory interval relief.

Fifteen hundred injections of tetraethylammonium were carried out without any serious toxic effects. One patient received 42,000 mgm. over a 6 week period. Caution should be exercised in giving the drug to hypertensives particularly those in whom the neurogenic component has been identified or suspected. Nonthypertensive patients in whom an overly labile sympathetic nervous system is anticipated require cautious administration of the drug. Undesirable falls in the blood pressure occur either immediately or after a delayed interval. Myasthenia may occur over a long period of administration but this disappears with the cessation of administration but anuric states the drug is inadvisable.

The authors postulated that the autonomic blockade may alleviate pain by means other than vasospasm namely altered tissue metabolism secondary to sympathetic block, or the blocking of certain afferent pathways in the autonomic nervous system.

W. FORTER MONTGOMERY M.D.

Vaughn, Arkell M.: Multiple Retrograde Saphenous Vein Ligation and Phlebectomy with the Aid of a Malleable Intraluminal Guide. *Surgery* 1947 31 51

In the author's experience high saphenous vein ligation combined with multiple retrograde ligations and excision of segments of the vein is superior to

high ligation and retrograde injection of a sclerosing solution. He reports the following as the basis for this superiority: (1) patients receiving retrograde injections were for the first few days more uncomfortable and disabled than those who had ligations only and (2) recurrences following retrograde injection were often due to incompetent communicating veins, recanalization of the thrombi following injection, or both.

Because the saphenous vein is often more difficult to locate around the knee than in the femoral triangle, a malleable guide was introduced into the lumen of the distal segment of the saphenous vein near the fema ovale. This can then be easily palpated and serves as a guide to exposing, ligating, and excising segments of the vein down the thigh and into the calf. This technique is described in detail and illustrated by numerous diagrams. The author recommends the use of longitudinal rather than transverse incisions for these multiple sites of ligation.

EDWARD H. CAMP, M.D.

BLOOD; TRANSFUSION

Brown, Herbert R., Jr.: The Distribution and Use of Human Whole Blood in the Pacific War. *U S Nav M Bull.*, 947 47 396.

At the onset of World War II human dried plasma and albumin were made available to the United States forces in adequate amounts but the demand for whole blood became increasingly urgent. At first blood had to be secured directly from service personnel but as demands increased it was necessary to transport and refrigerate whole blood from donors in the United States. The first large shipments of whole blood from the United States donor centers started in August, 1944 for the European theater and in November 1944 for the Pacific theater. The period covered by this report extends from November 19, 1944 to September 21, 1945. The increasing demands for whole blood in the Pacific theater presented special problems of long distances, tropical climates with attendant necessity for refrigeration, the preserving solution, and standard type of equipment. Distances were overcome by granting all whole blood shipments a No. 1 air priority. The refrigeration was maintained through the medium of a 50 cubic foot refrigerated box with water ice, and containing 16 pints of whole blood which could be maintained at a temperature of from 8 to 10 degrees C. for as long as 50 hours. A preservative anticoagulant solution, known as the acid-citrate-dextrose or Loutit-Mollison solution enabled blood to be safely stored and utilized up to 21 days from the date of bleeding and even longer in the case of emergencies. Standard donor and recipient equipment was set up with a bottle, being a vacuum type 600 c.c. bottle containing 480 c.c. of blood and 120 c.c. of anticoagulant solution. Finally studies on transported blood of ages from 4 to 31 days gave early assurance of the safety and practicability of this projected distribution and use.

The procurement for the blood collection program was made the responsibility of the American Red Cross with bleeding and processing being placed under the technical supervision of the Army and Navy. The program for the European Theater of Operation was under Army control and that of the Pacific theater by the Navy. In the operation of the program, all the blood was flown by the Naval Air Transport Service from Oakland, California, to Honolulu where it was received and then flown to Guam where the U.S. Naval Whole Blood Distribution Center No. 1 stored all blood in large refrigerators for a minimum of 12 hours and visually examined all bottles for hemolysis, contamination, and clots, discarding all unsuitable units. Visual inspection proved entirely satisfactory for the entire program. At the time of invasion, LSTH's were mounted with blood prior to proceeding to the target, and as required a complete blood distribution team would be put ashore with its independent 150 cubic foot refrigerator, a portable electric generator to supply current, an ice machine, and transportation facilities in the form of truck or jeep.

One hundred seventy-seven thousand seven hundred eighty four pints of whole blood were received at Guam from the United States, and a total of 171,564 pints were reshipped accounting for a 3.4 per cent over-all loss at the distribution center at Guam. The total weight of all shipments to Guam was 666,700 pounds or 483.35 tons and required a total of 65,557 cubic feet of plane space for the shipments. The Army in the Philippines estimated their whole blood needs to be 134 pints per wounded individual. In the Pacific Ocean area the estimates were calculated on a pint per total casualty i.e., killed, wounded, and missing, for a working hypothesis. Both methods were closely correct. It was necessary to estimate the daily requirements in advance. In considering the amount of blood required by different areas the Philippine Islands campaign required 93,086 pints, Okinawa 44,803 pints, Iwo Jima 16,324 pints, fleet units 4,508 pints, and all hospital ships 18,063 pints.

Reaction reports were gathered on a small portal card type of report form. A total of 21,106 reports were returned and of these there were 676 reactions with a resulting reaction rate of 3.1 per cent. In types other than O the reaction rates were above those of the type O recipients, thus lending weight to the desirability of adding types A and B group specific substance in order to neutralize the blood glutinins. It is realized that the optimum age at which blood may be safely transfused is 21 days although blood of 28 days of age and older may be and has been given with safety. It is generally agreed that the rate of red cell deterioration over the 21 day period rises rapidly but that at the 21 day period there still remains about 85 per cent of the initial red blood cell efficiency. The use of type O blood used in the Pacific was highly successful and in only a very few instances were crossmatchings carried out. It is stressed however that when possible

crossmatching is highly desirable and necessary. The highest reaction rate 7 per cent, appeared to be in patients with hookworm anemia. In a separate group of 381 reactions among 12,003 reported transfusions, there were 156 reactions (41 per cent of this series) reported on the cards as being allergic in type.

LEROY J. KLEINERMAN, M.D.

Hedenstedt, Sture: Elliptocyte Transfusions as a Method in Studies on Blood Destruction, Blood Volume, and Peritoneal Resorption. *Acta chir scand* 1947 95 Supp 138.

Since the autumn of 1944 Hedenstedt the author has been engaged in working out a method whereby elliptocytes (elliptical red cells) may be used as labelled corpuscles in studying blood destruction, blood volume and peritoneal resorption. The work of this monograph started after the author came across a case of elliptocytosis. By carefully performed transfusion experiments he has attempted to determine the lifetime of red blood corpuscles, the blood corpuscle volume, the blood volume, and, finally the resorption of blood from the abdominal cavity.

Elliptocytosis is an anomaly in which the red blood corpuscles are to a large extent elliptical in shape. The condition was first described by Dresbach in 1904. His case was that of a mulatto student in whom 90 per cent of his red blood cells were elliptical. The boy was otherwise normal. The condition is extremely rare occurring about once in every 2,000 or 3,000 people. The anomaly is apparently constant as the elliptocyte count remains the same over a period of months.

Investigations of the osmotic resistance of the red cells are important in distinguishing elliptocytosis from hemolytic anemia. Elliptocytes show normal or increased osmotic resistance as compared with red blood corpuscles in cases of hemolytic jaundice.

In the majority of cases of elliptocytosis described in the literature, the characteristic shape of the red blood cells is the only sign or symptom of interest. The white blood cells and the sedimentation rate are usually normal. Jaundice may be present occasionally. Other blood findings are normal on examination.

The idea of using elliptocytes as labelled blood corpuscles for experimental purposes seems only to have been employed in a few isolated investigations. The determination of the lifetime of red blood corpuscles according to different authors using different methods is reviewed and a wide variation of results is recorded. More recently investigators have tried to approach the problem of the life of the erythrocyte more closely by labeling the corpuscles with radioactive isotopes. Phosphorous, iron and nitrogen have all been employed for this purpose without a final and convincing solution to the problem. A discussion of possible sources of error is presented and reasons for inaccurate results are postulated.

The method of using naturally labelled red cells such as elliptocytes has been sporadically employed

by only a few investigators during the past 25 years. In the author's own experimental investigations he goes into elaborate detail and very meticulous measurements in presenting his technique and results.

By way of summary regarding the results of transperitoneal resorption of elliptocytic blood he concludes that elliptocytic red cells are resorbed from the abdominal cavity into the blood stream through the lymph vessels of the mediastinum at a uniform rate. Resorption of injected blood takes about 8 days. During and after the actual process of resorption the elliptocytic red cells are destroyed in the same way as though they had been injected intravenously (half of them die within 13 or 14 days). Intra abdominal adhesions need not occur even after repeated intraperitoneal injections of blood. Histological studies suggest that in man the red cells are resorbed through stomas into the subepithelial lymph lacunae in the diaphragm.

The author's experimental work is based upon 51 transfusions mostly in children with 10 elliptocytosis. The mixing time for the elliptocytes after transfusion amounts to about 15 minutes. Red cells disappear approximately according to an exponential curve and their half life is 13.1 ± 0.9 days.

The author describes a new method for determining the blood corpuscle weight and blood volume in man with the use of elliptocytes. The results of this unique method reveal the weight of red blood cells to be, on the average, $2.7-2.1$ per cent of body weight. And finally the determination of blood volume with this method is found to be $7.4-7.3$ per cent of body weight. Comparison of Hedenstedt's results with the results of other methods (radioactive phosphorous) reveal a significant difference of values for red cell weight. An explanation of possible reasons for this discrepancy is suggested.

This monograph is clearly presented and represents a novel approach to one of the many unsolved fundamental problems of biology and medicine. It is the culmination of much work well done.

EDWARD F. LEWIS, M.D.

Ginsberg, Harold, S.: Homologous Serum Hepatitis following Transfusion. *Arch. Int. M.*, 1947 79 555

With the ever increasing use of transfusions of blood and plasma the author deems it pertinent to emphasize the frequency of occurrence of homologous serum hepatitis following these therapeutic procedures.

In this article the literature is reviewed briefly. 14 cases of homologous serum hepatitis are reported with a detailed description of 2 fatal cases and their findings at autopsy.

The material presented comprised cases of hepatitis observed at the Seventh General Hospital from September 18, 1944 to November 14, 1944. The date of incubation of the disease as determined from the date from which plasma or blood was administered to the onset of symptoms ranged from 43 to 88 days with an average of 65 days.

The symptoms and signs, in order of frequency were malaise, nausea and vomiting, anorexia, dark urine, abdominal discomfort, jaundice, light to clay colored stools, fever, palpable liver, constipation, generalized aches and pains, chills, pruritus, polymorphic cutaneous rash, diarrhea, and palpable spleen.

The laboratory tests found to be most useful in the early diagnosis were the icteric index or test for serum bilirubin. These were also the most important tests in following the course of the disease. Examinations of the urine for bile and urobilinogen also proved to be useful. The determinations of the total plasma protein content, the albumin and globulin levels, and the prothrombin time were likewise valuable in following the course of the condition. There was a slight to moderate fall of the plasma protein content in all cases studied completely and in 1 case the level fell to 4.5 mgm. per 100 c.c. and the patient developed clinical ascites. In most cases there was a slight fall in the plasma prothrombin level but without need of the use of vitamin K. In the 3 fatal cases vitamin K was administered parenterally but no definite increase in the prothrombin time occurred.

The treatment of homologous serum hepatitis is similar to that of infectious hepatitis. High protein, high carbohydrate, and low fat diet is the basis of

therapy. Extra vitamins were administered in all cases, especially vitamin B complex. During the acute stages of the disease when nausea and vomiting were present, liver plasma, and intravenous injections of dextrose were utilized to supplement the insufficient diet.

The main clinical points of difference between homologous serum hepatitis and infectious hepatitis are the period of incubation, mode of spread, and severity. The period of incubation in the majority of cases of homologous serum hepatitis ranges between 60 and 90 days. Homologous serum hepatitis is spread by the parenteral injection of human blood or its products by means of transfusions, convalescent serums, vaccines, and contaminated syringes. The mode of spread of infectious hepatitis is not definitely known but presumably it may be transmitted by air borne droplets and the ingestion of material, i.e., food and water contaminated by the virus. The severity of homologous serum hepatitis is greater than that seen in infectious jaundice.

Biopsies of material aspirated from the liver during the course of these 2 diseases show that the pathologic changes are indistinguishable and the clinical pictures, likewise, have no definite features to aid in the differentiation of these entities.

JORN H. MORGENTHAU M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Clark, John H.; Nelson, Woodrow; Lyons, Champ; Mayerson, H. S.; and DeCamp, Paul: Chronic Shock; The Problem of Reduced Blood Volume in the Chronically Ill Patient. *Ann. Surg.* 1947 125 618

The authors have introduced the term chronic shock to designate the syndrome characterized by weight loss, decreased blood volume, decreased blood proteins, increased interstitial fluid volume, and increased susceptibility to shock correctable by transfusion and replacement of the blood volume deficit. The purpose of this series of 3 articles is to present the rationale and factual data upon which this syndrome is postulated.

Previous reports emphasized the coincidence of protein depletion and diminished blood volume but proof has not been incontrovertible that the latter is the consequence of the former nor has there been sufficient recognition of the fact that in evaluating the extent of protein depletion an accurate appraisal of the blood volume is mandatory.

Osmotic pressure of the blood protein and tissue tension are the factors which normally maintain the plasma volume in the ratio of 1:3 to the interstitial fluid volume via the interchange of fluid across the semipermeable capillary wall. However, numerous clinical observations relative to a change in this ratio despite an unvaried concentration of plasma protein would seem offhand to invalidate this thesis. Despite the complexity of the mechanism in operation, further consideration reveals the source of this apparent discrepancy.

Protein depletion should, by virtue of the dynamic equilibrium of protein, affect not alone the concentration in the blood but that in the tissue as well. A loss of tissue protein results in an increase in interstitial fluid volume and a reduction of tissue tension. This, then, shifts the burden of maintaining plasma volume solely on the hygroscopically active concentration of the reduced total mass of plasma colloids and consequently diminution of plasma volume follows. Some investigators have emphasized an alteration of the physiologic integrity of the capillary wall. Anemia, reduced total mass of hemoglobin is known to favor a loss of fluid and protein from the vascular to the interstitial fluid compartment.

An analysis of the study of 9 depleted soldiers revealed a lowering of the usual 1 to 3 ratio this alteration not being in proportion to the weight lost, but a correlation did exist of the weight lost, reduced plasma volume, and reduced total mass of circulating blood proteins, both hemoglobin and plasma proteins. This indicates that in patients with weight loss the reduced plasma volume may mask deficiencies in the total mass of both circulating

hemoglobin and plasma proteins. Biochemists have long stressed the fallacy of assuming that solute concentrations reflect the plasma volume. Therefore appraisal of the weight loss in terms of protein depletion and reduced blood volume permits a more accurate evaluation of the 'poor risk' patient than measurements of the concentration of hemoglobin and plasma protein alone.

To further invalidate criticism of the significance of plasma volume determinations, the ratio of the plasma volume to the interstitial fluid volume as well as serial determinations of the blood volume were studied in 4 normal individual patients. A decided constancy was obtained. This was further emphasized by the demonstration of a return of blood volume to a high level during the convalescence of a depleted patient, an effect repeatedly observed as a prelude to any appreciable recovery in weight.

Thus the concept of chronic shock becomes useful also in the comprehension of apparently conflicting clinical studies and in the formulation of new investigative programs of clinically pertinent problems.

Among the problems engendered by depletion of the body proteins, reduction of blood volume is of prime surgical significance. The purpose of this article is to consider the quantitative aspects of the red blood cell and hemoglobin deficits in chronic shock and the quantitative correction of these deficits by whole blood replacement. This required blood volume determination for as was emphasized above reduced plasma volume may so mask an anemia as to vitiate the results of such simple determinations as the concentrations of the hematocrit, hemoglobin and red cell count.

Eighty-nine patients with a clinical history of weight loss from malignancy or chronic infection, had initial determinations of body weight, plasma volume, hematocrit, hemoglobin concentration, and plasma specific gravity, 50 having repeated determinations. Sixteen normal subjects were also studied and of these 9 had repeated determinations. All laboratory procedures were carefully standardized.

Normally the blood volume determination can be calculated safely from the observed weight. In the depleted patients however the authors found the results to be more reliable when the usual weight standard provided extremes had not existed previously. All cases with weight loss revealed a plasma volume reduction approximating 25 per cent and an even greater reduction of red cell mass and total hemoglobin often approximating 50 per cent.

Since the rate of synthesis of new hemoglobin is known to be limited despite its priority on protein only by the administration of whole blood can anemia be corrected rapidly enough to permit urgent surgery. This also deviates available protein to the

more rapidly accomplished synthesis of tissue and plasma protein.

It was found to be clinically practicable in 10 cases to restore the blood volume by transfusion to the standard value for the patient's usual weight (often up to 150 per cent of normal for the observed weight) without evidence of significant hemoconcentration or overloading of the vascular reservoir. Two typical experiments indicated that this increment not only preceded any significant weight gain but was maintained during convalescence as a result of the gain in red cell volume. This supports the significance of the reduced effective blood volume in the patient with weight loss, e.g. chronic shock. Failure of blood volume restorations despite quantitative transfusion therapy indicates continued bleeding.

If blood volume studies are not available the total circulating hemoglobin and red cell mass cannot be evaluated accurately and therefore adequate restoration cannot be accomplished quantitatively. In this event, the authors suggest that since restoration to normal is often attended by definite but asymptomatic hemoconcentration correction of the masked anemia may be attained by transfusion toward this goal. They also found that a hematocrit of 50 per cent consistently indicated restoration of blood volume values to the standard level.

Quantitative correction of blood volume deficits by whole blood transfusions increased the tolerance of the "poor risk" patients for major surgical procedures.

Anemia and nutritional depletion are recognized features of neoplastic cachexia. Progressive anemia is more often apparent clinically than is the loss of tissue protein in the patient with advancing neoplastic disease. Among the factors considered in the genesis of anemia are continued bleeding, nutritional disturbances, bone marrow metastasis, and inhibition from an agent elaborated by the malignancy which may also elaborate a hemolytic agent. The purpose of this report is to present observations on the quantity and quality of the circulating blood in patients with malignant disease.

Blood volume studies were performed on 38 patients with malignancy 23 of whom had repeated determinations. The diagnosis was confirmed in all cases by histologic examination of tissue removed at operation.

Deficiencies of the total circulating red cell mass and hemoglobin were the major factors productive of the reduced blood volume found. The plasma volume deficit was decidedly less marked usually and in general, correlated with the total plasma proteins. Thus the changes are probably the result of deficiencies in red cell mass and hemoglobin without consistent depletion of the tissue protein reservoirs. This would explain why anemia may persist despite the administration of a copious supply of protein if whole blood replacement is withheld.

In malignant disease as in chronic sepsis, there is a fundamental disturbance in hemoglobin metabolism, the nature of which remains to be elucidated.

DAVID H. LEXER, M.D.

Rehn, E.: Rational Prevention of Thrombosis to Eliminate Embolism in Surgery (Ueber die rationelle Thrombosebekämpfung an einer emboliefreien Chirurgie). *Dtsch. med. Wschr.* 1947 73 18.

Since a strictly clinical approach to the problem of thromboembolism is necessarily limited efforts have been made at the author's clinic to correlate the clinical phases of the problem with chemico-biologic studies and to apply these principles as a step toward embolus free surgery. Every surgical procedure of the highest technical perfection is limited by the capacity for response of the subject's organism as a whole. This response may be measured in part by the efficiency of the circulation. Any surgical procedure influences the metabolism and induces changes in the circulation during the period immediately after operation. The sympathetic nervous system, in turn, may be so profoundly affected that disturbances of the system may be manifest immediately and for days after the operation. Operative trauma may lead to shock or to later complications such as collapse thromboembolism and pneumonia. The development and degree of complications depend upon the severity, the kind, and the site of operative trauma, but the stress or condition of the sympathetic nervous system of the patient plays a basic role in postoperative disturbances.

The author recognizes an "embolus type," the patient who has a constitutional predisposition to embolism but who lives a lifetime before the damaging insult leading to embolism occurs. On the other hand a severe disturbance may produce a definite syndrome and tendency toward embolism in a few hours or days. Ordinary factors predisposing to embolism are cachexia following illness or age, hormonal disturbances, severe anemia, uremia, and other severe organic disturbances. The particular surgical lesions associated with embolism are malignant tumors, empyema, diseases of the biliary tract, osteomyelitis and decompensated prostatic hypertrophy. General factors are exhaustion from hunger, thirst, cold and physical and psychical weakness. Another predisposing factor is circulatory lability of central origin from the late effects of influenza and diphtheria. In such cases the electrocardiograph may indicate latent toxic damage.

A more or less definite clinical picture is frequently present but pulse and blood pressure changes may be misleading in the differentiation of some underlying constitutional hazard from shock and collapse. Circulatory phenomena may give a fleeting warning and quickly disappear but they often tend to persist so that they are overcome only gradually or with difficulty. This constitutional hazard is, like shock and collapse, an expression of a determinate condition of the sympathetic nervous system, and its great significance to the surgeon is that it is linked with demonstrable circulatory weakness. Nonspecific tests of the carbohydrate metabolism and the alkali reserve of the blood are of value because their very unspecificity indicates disturbances from a variety of causes, which may lead to thromboembolism.

The fact that obliteration of the endolymphatic duct to this extent did not appreciably affect the volume of endolymph in the remainder of the system in a period of 3½ months rules out the hypothesis that hydrops of the labyrinth can be attributed to impairment of function of this structure

JOHN F. DILLON, M.D.

NECK

Seldin, S. M., Marinelli, L. D. and Oshry, E.: Radioactive Iodine Therapy. *J. Am. Med. Ass.*, 1946, 133: 838.

A patient was completely thyroidectomized for malignant adenoma in 1925 and 15 years later hyperthyroidism and severe back pain developed. In October 1939 a pulsating metastatic thyroid adenocarcinoma was removed from the region of the twelfth thoracic vertebra. The hyperthyroidism continued to progress for the next 2 years and metastases were demonstrated with x rays in the lungs, the right femur, the second rib on the left side, the left ilium, and the skull. Roentgenological therapy was ineffective. In March 1943 a tracer dose of radioiodine was shown to be taken up by all the metastases. Between May and August, 1943 a total of 102 millicuries of I^{131} (half-life 12.6 hours) and 20.5 millicuries of I^{131} (half-life 8 days), prepared in a cyclotron by bombardment of tellurium with deuterons, was given as sodium iodide in water. The estimated dose to the tumors was 10,600 equivalent r and to the blood 70 equivalent r.

Most of the radioactive iodine was taken up by the metastases. Time concentration curves were constructed for the tumor, blood, and urine. Additional treatment in April, 1944 and March, 1945 resulted in relief of the pain and the patient was in good condition at the time of the report.

CARROLL H. THOMAS, M.D.

Bartels, E. C., and Bell, G. O.: Thiouracil: Preoperative Use in 400 Patients with Severe Hyperthyroidism. *West J. Surg.* 1947 55: 39.

Thiouracil was used during the last 3 years in the preoperative treatment of 400 patients with severe hyperthyroidism. These patients represent about 35 per cent of all patients having thyroidectomy for hyperthyroidism. All patients were not prepared with thiouracil therapy. Three hundred thirty-eight cases were classified as primary hyperthyroidism, and 62 were classified as toxic adenomatous goiters. Table I shows the breakdown of evidence of severe hyperthyroidism. Table II shows a breakdown of the significant complicating diseases in 400 cases.

Thiouracil was administered in a total daily dose of 0.6 gr. It was found that full control of hyperthyroidism is essential before thyroidectomy. If full control does not take place, then any of the usual complications may arise. Thiouracil treatments should be individualized. Roughly it was found that 1 day of thiouracil treatment was needed for each percent age elevation in the basal metabolic rate. A patient

with primary hyperthyroidism of short duration and one who has had no iodine, will have a daily drop of about 1 per cent in basal metabolism. Patients with primary hyperthyroidism of long duration or of short duration who have received iodine therapy, will have a daily drop of 1 per cent in basal metabolic rate.

Patients with adenomatous goiters, who have had no previous iodine therapy will show a 0.64 daily drop in the basal metabolic rate; patients with adenomatous goiters who have had previous iodine therapy will show a 0.45 daily drop in the basal metabolic rate. At surgery the thyroid gland was found to be very soft and vascular when only thiouracil had been given preoperatively. To overcome this difficulty Lugol's solution was combined with thiouracil, thus making the surgery more satisfactory. Table III shows the reaction to thiouracil in 400 cases. A total of 35 cases showed white blood cell depression, fever, skin eruption, edema of the skin or swelling of the salivary glands. A chart is included, which shows the time of reaction to thiouracil. The time of onset of reactions varied widely except for the fever reaction which occurred on the ninth or tenth day. Both total and differential counts are necessary and these are repeated at 7 to 10 day intervals during thiouracil therapy. When agranulocytosis develops, energetic penicillin treatment is advised as protection against infection during the vulnerable period. Of 12 patients sensitive to thiouracil, 11 tolerated thiobutylal. The advantages of thiouracil preparation are that the patient is restored to a normal state of health for thyroidectomy; the need of multiple stage operations is eliminated, and the treatment has practically abolished mortality. Also the postoperative course of the thiouracil-treated patient is less stormy.

Two hundred sixty-six patients have been followed from 6 months to 2 years following thyroidectomy. Among these there have been 5 cases of recurrent hyperthyroidism. 8 patients have persistent postoperative myxedema; there have been 3 cases of unilateral cord paralysis and 3 patients have developed progressive exophthalmos. There was 1 postoperative death and 1 death from agranulocytosis due to thiouracil, a mortality of 0.5 per cent.

ROBERT J. BARNETT, JR., M.D.

Ross, E., and McConnell, J.: Thiouracil in Thyrotoxicosis—Results of Prolonged Treatment in 25 Cases. *Am. J. Med. Sc.* 1947 3: 74.

The authors' patients were under observation for from 10 to 3 months. On the basis of results, they were grouped as follows:

Group 1 includes 16 patients in whom sustained remission followed the cessation of thiouracil therapy. There were 15 females and 1 male. Three patients were in the second decade of life, 1 patient was in the third, 3 patients in the fourth, 6 in the fifth, 2 in the sixth and 1 patient in the seventh decade. Thirteen patients were under observation for 1 year or more and 3 for more than 2 years. There were 13 with diffuse goiter and 1 with nodular goiter. The longest period of treatment with thiouracil was 10.8 months.

Surgical management of the problem of thromboembolism with clinical regard for the operative risk, the degree of operative trauma and the effects of anesthesia decreased but did not eliminate thromboembolism. More recently attempts have been made to influence the clotting process in the vessels themselves. Many such attempts because of lack of control have failed to prevent embolism or have led to postoperative hemorrhage. The author's clinic has been developing a method which would demonstrate threatened or actual thrombosis and has achieved success by correlating the prothrombin index (PTI) with the clotting time plotting daily values of each on a graph. An increase or release of thrombokinase in the circulating blood augments thrombin formation but the process is not unlimited being dependent upon the prothrombin level. The prothrombin level thus becomes the key to the whole problem of embolism.

It is significant that in a large number of freshly wounded young men who were poor operative risks because of the severity of their wounds thrombosis and, particularly embolism were very rare. This is attributed to the fact that any sympathetic lability in these young men was quickly obviated. The exceptionally rare cases of thromboembolism among recently wounded men can be considered as of constitutional origin. With the development of infection deficiency of liver glycogen decreased alkali reserve and circulatory lability a tendency toward thrombosis appeared and the author was able to demonstrate this with absolute precision through his control test. In addition to the factors of operative risk, disturbances in blood composition, metabolism and circulation emphasis has been placed upon changes in the vessel walls as contributing toward the development of thrombosis. However, in more than 300 operations on the major blood vessels including suture and transplantation, there were only 3 cases of massive thrombosis in 2 of which embolism followed. It is significant that thrombosis did not occur at the site of transplantation but at a distance.

Numerous clinical observations signify the importance of certain sympathetic stimuli and disturbances in the development of thrombosis and embolism. This is shown by the frequency with which embolism is associated with atmospheric disturbances and with severe psychic insult. The author regards a spontaneous alkaluria as a manifestation of vasolability and has observed it as a manifestation of a sympathetic reaction associated with psychic trauma. By use of the prothrombin index it was possible to distinguish sympathetic disturbances arising from sympathetic and parasympathetic stimuli respectively. Hyperprothrombinemia is a vagotonic phenomenon while hypoprothrombinemia indicates sympathetic stimulation. Plotting the curve of the prothrombin index gives a true picture of the sympathetic equilibrium or tension which no other method has succeeded in doing, and the author found a definite correlation between the sympathetic tension and the prothrombin index.

Thus, from the standpoint of etiology two forms of thromboembolism can be recognized. The first depends upon tangible factors inherent in operative risk which can be considered as predisposing to thrombosis. These factors are related to disturbances of the metabolism, organic changes, and circulatory abnormalities and are similar to the factors underlying shock and collapse. The second etiologic form lacks these organic and demonstrable abnormalities and has a sympathetic lability as its basis. It is in the latter form that psychic insults and conflicts play an important role. The author believes he has unequivocal evidence that this second form may remain fixed or be obviated. It is difficult to achieve methodical proof but this may possibly be established by further investigations on the relationship between sympathetic stimuli and the prothrombin index.

There are three stages to be recognized in the development of thromboembolism: (1) a predisposition to thrombosis, (2) impending or threatened thrombosis and (3) thromboembolism. The first phase predisposition is conditioned by shock, collapse, operative risk and constitutional factors. The second phase follows through the influence of operative trauma, anesthesia, psychic trauma, atmospheric disturbances, unrecognized sympathetic disturbances and hormonal stimuli. Thromboembolism then supervenes. The curve for the prothrombin index and clotting time indicates the transition from the stage of predisposition to the second stage of impending thrombosis and at this point sufficient time still remains to prevent massive thromboembolism. The curve also portrays the effectiveness of anticoagulation therapy and eliminates the danger of postoperative hemorrhage from overdosage. For immediate effect heparin is administered and for prolonged therapy dicoumarol is used.

Because of wartime necessity the author's clinic functioned in two divisions and the scarcity of anticoagulants led to and permitted the use of anticoagulants in only one of these divisions. Thus, the effectiveness of management in two large contemporary series of cases could be compared and controlled. In a group of 1,596 patients in the one division anticoagulants were used only in those with the strictest indications because of the scarcity of the material. There were 3 cases (0.32%) of thrombosis and 1 case (0.15%) of embolism which ended fatally. Only when the last of the available anticoagulant substance had been consumed did a fatal case of massive lung embolism occur. This patient was receiving dicoumarol preoperatively but therapy had to be discontinued. At the time of operation the curve showed the PTI to be rising and the clotting time to be falling. Postoperatively the PTI and clotting time indicated a propagating thrombosis. On the eighth postoperative day a massive lung embolism occurred and heparin was given but a fatality ensued. The author doubts that giving heparin earlier would have prevented eventual embolism. The case indicates that the critical phase of therapy is prophylaxis

below 6 ggm. on admission. There was a postoperative decline in serum protein in 93 per cent of the cancerous patients as compared with 83 per cent of the noncancerous patients. A lowering of serum protein followed after appendectomy in 69.6 per cent of cases and after cholecystectomy in 81.6 per cent of cases. In 38 per cent of the cancerous patients the low protein level was found to be due to a diminished albumin fraction whereas in 45.3 per cent both the albumin and globulin fractions were diminished. In only 35 per cent of the cases of cancer did the serum protein return to normal levels within the first 10 postoperative days. Postoperative decline in the serum protein was greater in the cancerous patients than in the noncancerous. The fall in the blood proteins can be accounted for on the basis of increased protein catabolism, decreased protein intake, surgical blood loss and possibly the effect of the anesthetic agent. No definite relationship could be established between liver function and the decline of blood protein. Hypoproteinemia was treated during the acute surgical phase by parenteral injection and/or jejunal alimentation. In the author's experience it was not possible during the postoperative phase to prevent the fall in serum protein by either of the latter methods. Serum proteins returned to normal only when the patient was able to take an adequate oral diet.

BENJAMIN G P SEAROFF M.D.

Moyer C. A., Levin M. and Klinge, F. W. *The Volume and Composition of Parenteral Fluids and Clinical Problems of Body Fluid Equilibrium*. *South. M. J.*, 1947 40 479.

Since even normal persons under certain conditions can exhibit well defined alterations in the volume or composition of their body fluids, it necessarily follows that seriously ill patients, not alone those with heart or kidney disorders, can be affected even more markedly. This communication offers evidence which indicates clearly that the non-discriminating use of parenteral fluids can be productive of serious consequences.

The administration of isotonic salt solution to a person deprived of all other sources of fluid may result in sodium chloride retention which, if in excess of 5 per cent of the usual weight will even tuate in signs and symptoms of pronounced illness. This is attributable to a higher concentration of salt by virtue of the diminution of the water volume in the body. The latter results usually from the person's inability to excrete the salt injected in a sufficiently higher concentration in the urine than its concentration in the infusate so that a volume of water equivalent to that lost insensibly through the skin and the respiratory tract cannot be abstracted from the administered solution. The failure to abstract enough water from isotonic salt solutions may also be due to the failure to give enough of it or to insufficient excretion of urine. Among those individuals unable to obtain sufficient water from the quantity of isotonic saline solution usually given (3000 c.c.) are those with severe trauma (operative

and accidental) the aged particularly those with occlusive arterial disease, and those with anemia, malnutrition or cancer.

By the substitution of a 0.6 per cent saline solution the tendency is lessened for the development of a relative water deficit because of the greater concentration of the glomerular filtrate. This is of significance whenever large combined salt and water deficits need correction. However under certain conditions even hypotonic saline solution will not prevent the retention of salt. A potassium deficit is probably accelerated by the excretion of large quantities of sodium chloride.

Finally a word of caution is given relative to the injudicious employment of glucose or water for these substances have been shown to be capable of producing serious illness whenever amounts are prescribed that are greater than the sum of the insensible loss of water and the maximum excretory capacity of the kidney for water. In the event of water intoxication the authors recommend the use of hypertonic saline solutions (from 3 to 5%) or hypertonic racemic sodium lactate (M/2 or M/3) especially if clinical acidosis is manifest.

DAVID H. LYON M.D.

Allen, Edgar V.: *Anticoagulants*. *J Am M Ass.*, 1947 134 333

Students of coagulation of the blood must give more attention to the desirability of impairing the ability of the blood to clot within the blood vessels. This statement is emphasized by the observation that hemorrhage causes much fewer deaths than intravascular coagulation of the blood. Experimental and clinical studies indicate that coagulation of the blood may be impaired by anticoagulants with the result that intravascular thrombosis usually can be prevented, hemorrhage occurs rarely when anticoagulants are used expertly.

What are the requisites for an entirely satisfactory anticoagulant for clinical use? Viewed in the light of present day knowledge the following are required: (1) lack of harmful side effects when used for short periods for months or for years (2) a predictable effect on coagulation of a specified amount of the drug (possibly based on estimation of the blood volume) (3) prompt control of its effect by a 'counter' drug in order to prevent and control bleeding (4) a method of calculating the effect on blood which is simple and rapid which will give consistent results and which can be performed satisfactorily by relatively unskilled technicians or physicians (5) effective oral administration and (6) low cost. The spread between the ideal and practical may be great, and for the time being the medical profession must be satisfied with less than that which is desired.

Heparin and dicoumarol are fairly satisfactory anticoagulants but they have deficiencies which make desirable a continued search for an ideal anticoagulant for clinical use.

The mode of action by which heparin interferes with coagulation of the blood has not been definitely

of the capillaries and venules (3) tubular casts of the products of intravascular hemolysis and (4) lesions due to infection.

The 2 principal pathologicophysiological mechanisms which are believed to cause this damage are shock and intravascular hemolysis. The significance of shock is twofold: prolonged shock produces irreversible tubular degeneration and causes extrarenal uremia. With a fall of the systolic blood pressure of 50 per cent the volume of the blood circulating through the kidney may be reduced 95 per cent. The result is oliguria or anuria with extra renal azotemia.

The significance of intravascular hemolysis is less well understood.

Precipitation of hemoglobin in the renal tubules and hence renal tubular necrosis is primarily dependent on antecedent damage to the tubules and not on the acidity or alkalinity of the urine or the amount of hemoglobin in the blood. This antecedent damage to the kidneys may be produced by ischemia, shock, or chemical poisoning. It is etiologically nonspecific.

There is a striking similarity between the hematuric "burn" kidney and the renal observations in other conditions characterized by intravascular hemolysis, such as those following incompatible transfusions of blood, hemolytic reactions to sulfonamide therapy and malaria. The crush syndrome kidney in which casts of a myohemoglobin are present exhibits a comparable picture.

It may be stated that, while the renal lesions following extensive cutaneous burns are usually of a minor secondary and probably reversible character with little danger to the patient, in a minority of cases more serious lesions are caused by prolonged shock or by a combination of shock and intravascular hemolysis or by infection, and these may lead to renal insufficiency, renal destruction and death.

HARRY W. FOX, M.D.

Gershbarg, Harbert: Some Observations on War Wounds; with Particular Reference to Stormy Fermentation. *Mil Surgeon*, 1947 100 505

Gas gangrene was studied by laboratory methods after débridement in 170 war wounds. Muscle smears as well as tissue cultures were taken in all of the cases. Cultures were incubated both in a milk media and in Brewer's fluid thioglycolate. Positive fermentation was found in 69 per cent of the wounds of the upper torso and in 70 per cent of the wounds of the lower torso which were in the majority. Muscle smears were positive in 49 per cent of the injured who were subjected to débridement within 12 hours of wounding whereas in those cases with débridement from 24 to 48 hours later positive fermentation occurred in 78 per cent. Muscle smears were of value in determining the relative degree of anaerobic contamination and in the detection of cases of anaerobic cellulitis. In 83 per cent of the smears showing clostridia, *welchii*, diplococcal and streptococcal

forms were also present. Penicillin given preoperatively and prophylactically did not delay the growth of organisms obtained by débridement. Hence the author was unable to evaluate the effect of penicillin in wound prophylaxis. Further of 14 casualties with proved gas gangrene, 8 had received varying amounts of penicillin prophylactically.

BENJAMIN G P SHAPIROFF, M.D.

Aristovskii, V. M.: Anaerobic Wound Infection. *Am. Rev. Soviet Med.* 1947 4 388.

From experience in the recent war the value of bedside bacteriologic analysis in instances of gas gangrene has been seriously questioned. This stems from such factors as variations in technique and in the failure of bacteriologic studies to provide an early and rapid recognition of anaerobic infection. Moreover, bacteriologists and clinicians are at variance as to the interpretation of findings. Whereas surgeons regard the presence of the *Bacillus perfringens* in a wound with a normal exudate as an indication for energetic treatment against impending gas gangrene, the author believes this is unjustified since from 80 to 90 per cent of the wounds containing the *Bacillus perfringens* do not eventuate in gas gangrene. Fundamentally the mere presence of a pathogenic microorganism in itself without concomitant predisposing factors is insufficient cause for alarm. Thus, gas gangrene is a clinical entity for which the bacteriologist may supply supplementary information.

For treatment to be most effective a rapid diagnosis is essential. This has justifiably placed a demand for reports within 24 hours a demand which seldom can be met if accuracy is not to be compromised. It presently requires from 3 to 4 days for a complete report which should include the study of aerobic as well as anaerobic microflora, and not only should a pure culture of the anaerobic agent be isolated from the wound but identification must be made on the basis of morphologic, cultural, biochemical, pathogenic, and serologic properties.

At present the need of a rapid method is admitted. Special media for the *Bacillus perfringens* obviate the need of isolating this organism in pure culture for study but unfortunately no analogous cultural tests for the other agents of gas gangrene are available. The specificity of serologic reactions such as agglutination suggested another method which did not meet expectations because of the great variability of serologic types of pathogenic anaerobes.

The situation is considerably better in regard to the immunologic reactions of gas gangrene toxins, which are characterized as a rule by species specificity (except *Bacillus perfringens*) and are independent of the serologic type. Toxin specificity has been used for rapid diagnosis but it is still too early to judge its clinical value. Preliminary data indicate that the test works in pure infection but in mixed (as in the majority of human cases of gas gangrene) the results are equivocal. Therefore specific toxins cannot be neutralized by antigangrene sera.

DAVID H. LYNN, M.D.

vestibular dysfunction in the different subjects. In the majority the symptoms were incapacitating. The symptoms usually persisted in an acute form for from 7 to 10 days and then subsided almost entirely. The disappearance of the acute symptoms occurred with striking rapidity sometimes within a period of 24 hours. In no instance did complete recovery occur with the subsidence of the acute symptoms. Instead the patients entered into a phase in which the symptoms were absent during ordinary activity but could be evoked momentarily by an unusual stimulus. In general the stage of latent vestibular dysfunction persisted for approximately 60 days and then disappeared. In no instance was streptomycin therapy interrupted because of vestibular dysfunction. A noteworthy feature of the reaction manifested by vestibular dysfunction was the fact that nystagmus was seldom encountered.

Deafness developed in 2 patients. The loss of hearing was virtually complete in 1 person and amounted to more than 50 per cent of total hearing in the other. In both instances the deafness occurred after the repeated intrathecal administration of streptomycin for the treatment of tuberculous meningitis. No tinnitus or impairment of hearing developed during or subsequent to the streptomycin therapy in any other of the 14 subjects. Neurologic examination was otherwise negative in all of the subjects.

Anemia did not occur but leucopenia without granulocytopenia occurred in 2 subjects in conjunction with the occurrence of a drug sensitivity reaction. It is doubtful if this phenomenon represents a toxic reaction to the streptomycin. Thrombocytopenia was never observed. There was no evidence that the administration of streptomycin resulted in any damage to the liver. Visual acuity was not affected.

It is believed that all the reactions are a consequence to the drug rather than to impurities.

The authors conclude that the immediate toxicity of highly purified streptomycin sulfate on long continued administration is sufficiently low to justify the use of the drug in the treatment of serious protracted infections, such as most forms of tuberculosis. However as streptomycin can produce potentially serious toxic reactions, it is inadvisable to use the drug in the treatment of generally benign infections such as recently acquired pulmonary tuberculosis of minimal extent.

LEROY J. KILGUSSEY, M.D.

Flory, Lady; Ross, R. W. N. L. and Turton, E. C.: Infection of Wounds with Gram Negative Organisms: Clinical Manifestations and Treatment. *Lancet* Lond. 1947 1: 855

The effectiveness of penicillin in eliminating gram positive organisms has brought to the fore the problem of dealing with gram negative invaders. At first these were considered of minor consequence in wounds. Yet, even if their toxic effects are minimal when not introduced into vitally dangerous areas the

present report indicates that their nuisance value in impeding repair is high.

This study concerns the observation of 63 lacerations involving bone, only 7 of which were completely closed by secondary suture or plastic repair and 10 superficial wounds. Of the 56 open wounds, 51 were found to harbor 1 or more species of gram negative bacteria from the second week of wounding onward, the other 5 healing comparably to a secondary closure. Since all patients received topical penicillin from the time of receipt of the injury throughout treatment, the gram positive organisms commonly considered responsible for major sepsis were of minor significance. Clostridia were a problem for a short period only.

In the early stages of uncontaminated gram negative infection no deleterious local effects, such as hindrance of epithelial growth were observed nor were there marked constitutional disturbances such as fever, anemia, sepsis etc. Its persistence however caused serious, if at times occult consequences as manifested by a characteristic thin brownish discharge which often possessed a putrefactive odor and by a tendency toward sinus formation and sequestration (21 of 53 cases). Ordinarily if a blood clot remains sterile it forms a basis for the ingrowth of organizing tissues but if infected with gram negative organisms (*Bacterium coli*, *Proteus* or *Pseudomonas pyocyanea*) disintegration steadily occurs leaving no foundation for repair. This appeared to be the reason for interference with the process of bony and soft tissue repair and the lack of union. The 10 surface lesions gave no evidence that gram negative bacteria had any clinical significance. *Bacterium coli* was the earliest invader appearing in 50 per cent of all wounds examined within the first week. *Proteus* appearing most often in the second week, and *Pseudomonas pyocyanea* in the third week or later.

Bacteriological and clinical effects of the daily local application of different drugs and therapeutic agents of promise were observed. Streptomycin was found to be the most effective in removing all 3 gram negative organisms both rapidly and permanently. Sulfathiazole was effective in eliminating *Bacterium coli* and *Proteus* to a lesser degree. Sulfamezathine had a similar effect on *Bacterium coli* and *Pseudomonas pyocyanea*. The presence of *Staphylococcus aureus* in the wound was almost as effective as the 2 sulfonamides in reducing the gram negative population nor was there any evidence that daily application of penicillin increased their number when they were the only organisms present. The majority of the remaining agents did not produce results consistent enough for them to be considered with the agents already discussed.

It was emphasized that reduction of infection was only obtained by cleansing of the wound in addition to the daily applications and by constant attention to the guiding principle that to produce the desired effect full access to the infected part must be obtained. Neither operation nor enclosure in plaster of Paris had any pronounced effect on the infection.

It was emphasized that reduction of infection was only obtained by cleansing of the wound in addition to the daily applications and by constant attention to the guiding principle that to produce the desired effect full access to the infected part must be obtained. Neither operation nor enclosure in plaster of Paris had any pronounced effect on the infection.

Group 2 comprises 13 patients as follows.

(a) Nine patients who have remained in remission during the administration of small doses of 0.1 to 0.2 gm. daily, but who relapsed when the drug was discontinued. Of these, 1 was a male and 8 were females; the duration of thiouracil administration was 1 year and the longest 19 months. Three of the patients developed moderately severe signs of edema and congestion of the lids and conjunctiva, and 2 exophthalmos.

(b) Two patients who relapsed when the dose was reduced to 0.2 gm. both of whom had nodular goiter without relapse. The first patient was a woman, aged 69, with nodular goiter, diabetes mellitus, moderate hypertension, congestive heart failure, and a basal metabolic rate of plus 46 per cent. Thyroidectomy was performed at the end of 11 months because of pressure symptoms. The second patient was a man, aged 32, with an initial basal metabolic rate of plus 50 per cent and a diffuse goiter. His goiter decreased in size over a period of 8 months.

Ten of the 13 patients in group 2 were in the third and fourth decades of life and 3 were in the sixth decade. Eight had diffuse goiter, 2 nodular and 3 recurrent postoperative goiter.

Group 3 comprises 6 patients (1 male and 5 females) who failed to show satisfactory response over periods of 7 to 15 months. Five patients were above 44 years of age. 4 had a complicating disease, such as acromegaly, hypertension, myocardial enlargement, diabetes, epilepsy, and auricular fibrillation.

Five of the 35 patients in the present series exhibited a leucopenia of less than 4,000 white cells per cubic millimeter. One of these following a period of abstinence, exhibited no recurrence of leucopenia when the drug was readministered. One had leucopenia several months after cessation of therapy; this was thought to be due to the hyperthyroidism rather than the therapy. One patient had a severe granulopenia, pharyngitis, and fever. One developed maculopapular dermatosis.

CLINTON H. TURNER, M.D.
Labey F. H.: Surgery of the Thyroid Gland. *N. England J. M.* 1947 336 46.

The author's review is based on his experience with between 25,000 and 26,000 operations on 22,000 to 25,000 patients with thyroid disease during a period of 30 years. The operative mortality was 0.73 per cent and the patient mortality 0.88 per cent. Thiouracil, thioarbitral, and propylthiouracil have been used preoperatively in a recent series of 500 cases, with a patient mortality of only 0.17 per cent. The author believes that these drugs interfere with the elaboration of thyroxine by the thyroid gland but states that the action of administered thyroxine is not altered at operation, however the gland is very friable and microscopically has the typical appearance of a toxic, hyperplastic gland, unless iodine is given the last 3 weeks before surgery when the hyperplasia regresses. At the Lahey clinic, Boston, it is now the practice to discontinue thiouracil 1 week before surgery to

avoid the possibility of agranulocytosis at the time of surgery. The average stay in the hospital before the thiouracil era (with iodine treatment preoperatively) was 55 days for the 3 stage operation, and 35 days with the two stage operation. With thiouracil and iodine the average stay is 8 days.

Complications due to these drugs are as follows: neutropenia, granulocytopenia, fever, skin eruptions, and enlargement of the salivary glands. These occur in 9 per cent of patients receiving thiouracil and in 28 per cent of those treated with thioarbitral. Experience with propylthiouracil included 60 patients submitted to surgery and 100 in preparation, with a showing leucopenia. When these complications occur and the drug is withdrawn until disappearance of the complication, readministration of the drug is associated with a greater hazard of recurrence. Agranulocytosis and neutropenia occurred as late as 8 days after the last dose of thiouracil, and as late as 9 months after beginning administration on as low a daily dose as 0.2 gm. Agranulocytosis is treated with penicillin, pyridoxine, and liver extract, with the greatest dependence on penicillin.

Apathetic hyperthyroidism is described as a chronic, low grade hyperthyroidism in older people usually with only a small increase in basal metabolic rate, with myasthenia and loss of weight. Subtotal thyroidectomy results in recovery.

The importance of subtotal thyroidectomy in "thyroid disease" is emphasized.

Other phases of hyperthyroidism discussed are myasthenia, exophthalmos, diminished liver function, cancer of the thyroid, variations in relations of re-current laryngeal nerve, intrathoracic goiter, and the use of lipocal in the control of diarrhea associated with hyperthyroidism.

CLINTON H. TURNER, M.D.
Figl, F. A.: The Etiology and Treatment of Cicatricial Stenosis of the Larynx and Trachea. *South. M. J.*, 1947 40 17.

In a group of 43 cases of cicatricial stenosis of the larynx and trachea, fracture of the cartilages and previous removal of tumors were the most common causes of stenosis. Other less frequent causes were acute infections, self inflicted and accidental severing of the trachea, and the use of nasal feeding tubes.

The stenosis was treated by an open operation, that is, by thyrotomy excision of the scarring and skin grafting in 27 cases, by continuous dilatation with or without incision of the scar in 10 cases, and by repeated incision of the cicatricial diaphragm in 2 cases. The treatment is described in detail.

Prolonged dilatation was carried out in all the cases after skin grafting.

In 24 of the 27 patients treated by skin grafting the lumen is ample, and in 22 patients the tracheotomy opening has been closed. In 8 of the 10 patients who were treated by continuous dilatation decannulation has been carried out. Both of the patients who were treated by repeated incision of a cicatricial diaphragm have at the time of this report, a free air way.

diphosgene which had been considered to be equivalent to that caused by oxygen consists in a lesion of the alveoli.

4 Exposure to oxygen aggravated the condition of animals with blast injuries of the lung

In interpreting the symptoms produced by exposure to oxygen in man the author concludes that sub-sternal distress is a manifestation of an injurious effect of the oxygen on the pulmonary tissue and the decrease of vital capacity is due partly to the dilating effect of the oxygen on the pulmonary vessels and partly to an exudation into the pulmonary tissue caused by oxygen at high partial pressure

Attention is drawn to the disturbance of the carbon dioxide carrying capacity of the venous blood that results when a normal subject inhales pure oxygen. It is suggested that the pulmonary damage in oxygen poisoning is caused by a disturbance of the carbon dioxide transport in the venous blood. The author's view of the pathogenesis of pulmonary damage may be formulated as follows. The oxygen entails an injurious effect on the lungs when the supply unduly exceeds the demand.

The bearing of such views on oxygen therapy is discussed. Long continued treatment of arterial anoxia with high concentrations of oxygen can safely proceed provided that the administration is adjusted to avoid a supersaturation with oxygen in the venous blood. The value of the increase of volume of circulating blood that is believed to occur during the first hour of oxygen inhalation is discussed in connection with shock. Attention is also drawn to the im-

portance of the dilating effect of the oxygen on the pulmonary vessels which may aggravate hemorrhagic pulmonary damage

The author considers that the views set forth may provide a more accurate background and open up extended possibilities for clinical oxygen therapy

MARY FRANCES FOX, M.D.

Collen William G and Griffith Harold R.:
Postpartum Results of Spinal Anesthesia in
Obstetrics. *Current Res Anesth.* 1947 26 114.

The postpartum results of 200 consecutive cases of spinal anesthesia for vaginal delivery have been carefully studied and compared with a similar series of 200 consecutive cases of gas anesthesia with cyclopropane or nitrous oxide followed by cyclopropane

The best results are obtained if the dose of spinal anesthetic agent is small and given in dilute solution. The authors use 5 or 6 mgm. of pontocaine in either 0.10 or 0.075 per cent solution. The incidence of spontaneous respiration and optimum oxygenation of the newborn is greatly increased and uterine blood loss during labor is greatly reduced by the use of spinal anesthesia. Headache does not occur more frequently after spinal anesthesia than after gas anesthesia, but it may be somewhat more distressing

It is emphasized that the services of a qualified medical anesthetist with some clinical experience in obstetrics is essential for success in the use of this method

MARY FRANCES FOX, M.D.

Fig. 3.

Fig. 3. (Blair) Hemosiderosis, giving rise to miliary mottling.

Fig. 4.

Fig. 4. Encysted effusion in the lesser fissure and the upper part of the greater fissure, as seen in the lateral view.

The areas of increased translucency are due to (1) pneumothorax, (2) emphysema (3) single or multiple air containing cysts (4) cavities and (5) diaphragmatic hernia.

The opacities may be subdivided as follows

1 Mottled opacities which may be localized to an area of lung or may be generalized throughout the lung. The former occur in phthisis although this form of tuberculosis is rather rare in children and in patchy pneumonitis. The latter is encountered in acute miliary tuberculosis, chronic miliary tuberculosis, leucemia and in the rare hemosiderosis (Fig. 3).

2 Rounded opacities which may be intrapulmonary, when they are caused by (a) primary tuberculous infection (b) hydatid cyst (c) congenital cyst, (d) solitary secondary deposit, and (e) primary neoplasm and extra pulmonary when they are caused by (a) neoplasm (b) fluid-containing cyst and (c) encysted effusion.

3 Homogeneous nonrounded opacities, situated in the pleura. These opacities in children are almost always due to either clear effusion or pus in the pleural cavity. A roentgen study in both postero-anterior and lateral views is indispensable (Fig. 4). Encysted interlobar effusions are rare in children.

4 Opacities of segmental origin. These the most common type of opacities in children are undoubtedly the result of a mixture of consolidation and collapse of the lung. They are seen in (a) inflammatory conditions such as a true lobar pneumonia atypical pneumonia, and the very common nonspecific pneumonitis (b) pressure of a tuberculous gland on the bronchus or ulceration of the gland into the bronchus, (c) inhaled foreign body and (d) primary neoplasm.

5 Linear opacities. Abnormal linear opacities encountered in the lungs are caused by accessory fissures such as the one associated with the lobe of the azygos vein by fibrosis by complete collapse of a small segment of lung or by bronchiectasis.

T. LEUCOTTA, M.D.

Jamison H. W., and Carter R. A.: The Roentgen Findings in Early Coccidioidomycosis. *Radiology* 1947 48 353.

A detailed roentgen characterization of early coccidioidomycosis has been accomplished largely because military necessity required the stationing of troops in certain endemic areas. Because the Medical Corps was aware of this hazard thorough case studies, including laboratory and x-ray findings were made.

The diagnosis in endemic areas is not difficult; the sporadic cases require an alertness on the part of the clinician to its possibility. It has been established that riding through an endemic area (the San Joaquin Valley of California, Arizona, and parts of Nevada, New Mexico and Western Texas) may be followed by infection; hence such a diagnosis should be considered in any patient having a respiratory infection and giving a history of being in or through such an area. An intradermal test with the use of a 1 to 100 concentration of a potent extract will be positive in all but a few of the more severe disseminated infections. This presumptive diagnosis is established by positive precipitation or complement fixation tests, though final proof is obtained by demonstration of the organism from sputum culture or guinea pig inoculations.

Clinically influenza and primary atypical pneumonia present somewhat similar symptoms and find

ings including local or general aching, weakness, sore throat, indefinite gastrointestinal disturbance, cough, a temperature of from 100 to 102 degrees, a white blood count of 10,000 to 12,000 with a mild increase in neutrophils. However, in early coccidioidomycosis there is frequently an eosinophilia and chest pain is present in a high percentage of the patients.

The fibrile reaction is usually over in from 3 to 10 days, though a chest roentgenogram may still show a considerable residual infiltration. One to 2 weeks later from 2 to 20 per cent of the patients develop skin lesions, some characteristic of erythema nodosum, others *erythema multiforme*. Acute arthritis and conjunctivitis may accompany these allergic skin manifestations.

The roentgen findings in acute primary coccidioidomycosis are not specific. The lesions are quite similar to bronchopneumonia, primary atypical pneumonia, rheumatic pneumonitis or tuberculosis. A roentgenogram of the chest made at the time of onset will show some pulmonary infiltration in about 90 per cent of the cases. The degree of infiltration varies from slight haziness of the hilar shadows to extensive consolidation of a major portion of a lung field. The infiltrations vary in density, are mostly unilateral, homogeneous, usually hilar or basal in location and show little tendency to lobar distribution.

If the infection persists, the symptoms (low grade fever, weakness, fatigability, chronic cough, chest pain, weight loss, and sometimes hemoptysis) may closely resemble those of tuberculosis. The roentgenogram may be misleading if the lesion is in the upper lung fields, especially since cavitation also occurs in coccidioidomycosis. The differentiation is dependent on the bacteriological and immunological findings. Although 85 to 90 per cent of the cases clear in from 2 to 6 weeks, some have persisted for over 2 years.

Other slowly resolving pulmonary lesions including histoplasmosis and torulosis must be excluded.

Mediastinal adenopathy is uncommon in the usual acute transitory infections and is almost never seen in the focalized infections of the nodular or cystic types; however, approximately one third of the cases of persistent pneumonitis and practically all fatal cases have an associated mediastinal adenopathy.

Pleural effusion is frequently present. It is ordinarily small in amount, and fleeting, but it may be massive and persistent.

Residual coccidioidal foci may persist in the lungs as single or multiple nodules 1 to 4 cm. in diameter, and sharply circumscribed, or as isolated thin-walled ringlike cavities 1 to 3 cm. in diameter. The latter are sometimes mistaken for congenital cysts. Cases resulting in nodule formation are usually no more severe or prolonged than those in which the infiltration clears completely, the exception being those presenting multiple areas of infiltration followed by multiple nodule formation. In these cases the onset is typically quite severe. By contrast, those cases in which cavities develop present typically more severe initial symptoms. Cavitation may develop from the

area of the pneumonitis or from the excavation of nodules. In the latter case the cavities are usually smaller and have thicker walls. Cavitation and/or nodule formation may occur in from 3 weeks to 3 months after the initial pneumonitis. The nodules and cavities are benign in character and are uniformly slow in evolution, some lasting as long as 2 years, with no appreciable change in size. Some of the nodules eventually calcify. These residual foci are usually found on routine examinations. The roentgenograms are in marked contrast to the clinical and laboratory findings, which are normal. In the presence of cavitation, however, the organism is usually recovered from the sputum with no difficulty. Most coccidioidal cavities are easily identified in endemic areas. The typical finding is a solitary thin-walled ringlike shadow without surrounding infiltration. In a few cases, however, the condition cannot be differentiated from tuberculosis. In other cases it resembles a pyogenic infection.

The roentgen findings in disseminated coccidioidal infections are primarily those of mediastinal adenopathy, associated with varying degrees of pulmonary infiltration. Massive confluent miliary disease may be present with multiple areas of bone destruction. The chronic form of the disseminated type of the condition may have draining sinuses or chronic coccidioidal osteomyelitis.

R. B. Lewis, M.D.

Wellin, S.: The X-Ray Diagnosis of Cholesteatoma in the Temporal Bone. *Brit. J. Radiol.* 1947 20 192.

As a rule, cholesteatoma cannot be diagnosed roentgenologically until bone destruction has set in. Therefore a detailed anatomical picture of the temporal bone obtained in several projections is essential.

The author uses the four projections of Runstrom together with the projection of Towne which permits a simultaneous viewing of both sides.

In the projection of Towne the roentgenogram is made with the patient lying on his back, the chin a little drawn in, and the central ray tilted 35 degrees toward the feet.

In the four projections of Runstrom the following procedure is applied:

In the first and second projections the patient is lying on his side and stereoscopic roentgenograms are made with the central ray tilted 25 and 35 degrees, respectively, toward the feet. In the third projection, which is a modification of the original Stenvers projection, the patient likewise lies on his side but the central ray is tilted from behind forward at an angle of 30 degrees and from 5 to 10 degrees cranially. The fourth projection is the well known standard submentovertical projection.

The author describes in detail the roentgen appearance of the various structures of the temporal bone in all these projections, and uses photographs of anatomic specimens and typical roentgenograms for the purpose of illustration.

The roentgen diagnosis of cholesteatoma was originally considered easy, but experience shows that

many great difficulties are involved especially when the cholesteatoma is located in pneumatized bone structures.

One may consider the following findings as rather characteristic the sharp definition angularity and polygonal shape of the cholesteatoma cavities their occurrence in temporal bones with reduced pneumatization and the presence of a linear calcareous zone between the cholesteatoma and the surrounding bone tissue. The author found that there are some other roentgen findings which may also be used advantageously. These vary according to the site of the cholesteatoma in the external auditory canal attic, aditus eustachian tube, or antrum.

A cholesteatoma of the external auditory canal is rarely subjected to roentgen examination unless an extension into the tympanic cavity is suspected. An enlargement of the external auditory canal as compared to the opposite side and superficial destruction of the walls are occasionally noted.

The cholesteatoma of the attic may lead to 3 different pictures at times there is a destruction of the lateral wall at other times the destruction is localized in the ceiling and last if the cholesteatoma grows backward toward the aditus there may be destruction of the walls of the aditus. If a cholesteatoma develops in the epitympanic recess a well defined spikelike or rounded defect is observed in the lower margin of the attic.

The cholesteatoma of the aditus is characterized mainly by an enlargement of the aditus. Later this is followed by destruction of the walls and extension into the antrum cavity. In practically half of the author's cases a diagnosis of cholesteatoma was made on the basis of changes in the aditus alone.

In cholesteatoma of the eustachian tube a typical finding is a pathologic dilatation of the tube with sharp outlines.

A cholesteatoma in the antrum is diagnosed with some difficulty since the size of a normal antrum varies to a great extent. The problem is further complicated if the temporal bone is pneumatized. The projection of Towne (or the almost identical projection of Holmes) helps here considerably because it permits a comparative study of the two sides. If the cholesteatoma cavity is small, diagnosis is impossible provided there is not also a pathological enlargement of the aditus. If the destructive zone is large a differentiation from abscess cavity must be considered. A sharp circumscribed margin of the cavity with associated changes in a sclerotic temporal bone is indicative of cholesteatoma. T. LECOTIA, M.D.

List Carl F. and Hodges, Fred J.: Differential Diagnosis of Intracranial Neoplasms by Cerebral Angiography *Radiology* 1947 48 493.

Due to differences in vascularization of intracranial tumors angiography not only permits a localization of most tumors but also furnishes information as to the nature of the neoplasm by demonstrating a specific vascular pattern. In this respect the method is decidedly superior to ventriculography.

Egas Moniz and his pupils were the first to describe characteristic angiographic findings in angiomas meningiomas, and certain vascular gliomas whereas in cysts abscesses, and cholesteatomas they noted a conspicuous absence of the blood vessels. Later similar observations were made by other investigators.

The authors in a series of 125 cases at the University of Michigan Hospital found a typical vascular pattern in the following groups: angioma, meningioma, glioblastoma and certain types of astrocytoma. It must be mentioned, however, that a negative report does not necessarily permit an exclusion of these lesions, but a positive report is almost pathognomonic.

Angioma (8 cases) Most of the lesions in this group are arteriovenous malformations. The angiograms as a rule show one or several enlarged and unusually tortuous arteries leading to a tangle of smaller vessels from which one or more greatly dilated and redundant veins emerge. Because of the numerous arteriovenous connections the entire vascular malformation is visualized during the arterial phase of the angiography and there is no filling during the venous phase. Other characteristic signs are that vascular malformations, in contrast to true neoplasms, do not displace the uninvolved cerebral vessels and that angiomatous vessels are far more bizarre in size than those encountered in vascular neoplasms. Cavernous angiomas of the brain without associated vascular malformation are rare and their angiographic appearance is inconclusive. The authors did not have a chance to observe an intracranial angioblastoma which occurs almost exclusively in the cerebellum.

Meningioma (20 cases) The angiographic pattern of the meningiomas depends somewhat on the location of the tumor. As a whole since most meningiomas are demarcated and globular, they cause a characteristic type of vascular displacement. The cortical arteries in contact with the tumor appear to be distended and separated from one another where as the arteries of the adjacent compressed brain are crowded together and form a concentrically arranged corona around the lesion. In frontoparietal meningiomas this is best demonstrated in anteroposterior arteriograms whereas in meningiomas of the olfactory groove the appearance is visualized to greater advantage on the lateral arteriogram. Since the meningiomas obtain their blood supply from both the external and internal carotid (and vertebral) systems a combination of angiography of the external (or common) carotid artery and of the internal carotid artery is of definite value. The external carotid artery provides the extracranial and dural circulation of the meningiomas. The supplying arteries are apt to be enlarged and tortuous they end in a dendritic cluster of smaller vessels which often perforate the bone leading to negative imprints in the calvarium on the simple roentgenograms and to a nerve end like arborization on the arteriogram. The internal carotid (and less frequently the vertebral) artery supplies the intracranial circulation of the meningioma. Besides the normal but displaced cortical

cal arteries, one may observe one or multiple newly formed "tumor vessels" which split up into finer branches giving on the arteriograms a paint brush or flower spray appearance. The venogram shows large but short veins with many tributaries along the circumference of the tumor in a garland or claw like fashion. Not infrequently due to the very rich capillary vascularization of the meningioma, a rather diffuse opacification silhouetting part of the growth or even the entire growth is observed.

Glioblastoma (55 cases) According to various investigators glioblastoma leads to a typical angiographic appearance in 40 to 64 per cent of the cases when the peculiar vascular pattern is directly pathognomonic. Hardman distinguishes four different zones of blood vessel structures in glioblastoma which: (1) an infiltrating tumor often undergoing extensive central necrosis. There are (1) the zone including the brain tissue adjacent to the neoplasm in which the vascular pattern is normal, although some what dilated (2) the invading zone showing glomeruloid microaneurysmal disruption of the angioarchitecture, (3) the deeper still viable zone containing sinusoid vessels larger in size but fewer in number and (4) the central necrotic or cystic zone in which are blood vessels which are thrombosed and hyalinized. The angiographic changes are observed in the second and third zones. The authors describe two types of special vascular pattern. In the first type the network of the fine crisscrossing capillaries and of the few larger sinusoid vessels resembles the roentgenographic picture of a normal lung, although it is more irregular and spotty. The second type is characterized by a very coarse and bizarre appearance of the blood vessels similar to that seen in the arteriovenous malformations, but no well defined afferent arteries and efferent veins can be distinguished and there is always displacement of the adjacent normal vessels of the bulk of the tumor.

Astrocytoma (12 cases) Since astrocytoma has a tendency to interstitial liquefaction and formation of cysts the blood supply is relatively scanty and therefore it is not demonstrated too well by either histologic or angiographic methods. In addition there is extensive stretching and spreading of the larger and medium-sized cerebral arteries.

The conclusion is reached that in the four groups of tumors described a preoperative study of the vascularity of the lesion is of great aid not only for establishing surgical indications but also for planning the operative attack. T. LECHE, M.D.

Gardini, G.: X Ray Therapy of Operable Cancer of the Vocal Cords. Eighteen cases Treated in the Period from 1921 to 1948 (La röntgen-terapia del carcinoma della corda vocale operabile. Su 8 casi trattati dal 1921 al 1948) *Radiol. med.*, Milan 1947 33 25.

Surgical removal is the accepted method of treatment of endolaryngeal tumors, x ray therapy being used only for inoperable tumors, postoperative recurrences, or metastases in the lymph glands.

Cancer of the vocal cords appears in the form of pedunculated tumors, leukoplakia, or ulcers, and may spread toward the anterior or posterior commissure.

Carcinoma of the vocal cords is considered a radio-sensitive tumor, and Coutard suggested various methods of treating it. From 6,000 to 7,000 centners roentgens may be applied within 6, from 13 to 16 or 50 days in the form of daily treatments. In order to avoid epidermitis it is generally advisable to reduce the daily dose and to prolong the duration of the entire treatment. The author uses the following technique: 180 kv., 1 mm. of copper as filter 10 ma., from 50 to 60 cm. focal distance 300 roentgens daily alternation of the port of entry and the use of only 3 irradiation fields. The entire skin dose ranges from 6,000 to 8,000 roentgens and is given within 6 weeks.

The author reports 18 cases in which operable cancer of the vocal cords was treated with x rays with good results. Twelve patients were alive 5 years after treatment. JOSEPH K. NARAY, M.D.

Garland, L. H.: Pulmonary Sarcoidosis: The Early Roentgen Findings. *Radiology* 1947 43 333.

The pulmonary manifestations of sarcoid include lymph node enlargement, miliary or nodular lung densities or a combination of nodal enlargement and pulmonary infiltration. The disease is insidious in onset and tends to run a chronic relapsing course. Usually the constitutional symptoms are mild, though occasionally severe even fatal cases occur.

The author has summarized the literature in respect to the histological changes and the pulmonary findings. He presents 36 cases of sarcoidosis 33 of which were verified by histological examination. Several were discovered incidentally in routine roentgenogram of the chest. Approximately one half of the patients were in their twenties the others ranged from 11 to 74 years of age. Twenty two were females 14 were males 21 were white 15 were colored. Ten patients had only pulmonary lesions. The pattern of lung involvement was extremely variable ranging from true miliary densities, through coarse nodulations and apparent linear fibrosis, to coalescent cirrhotic or pneumonic shadows. There is nothing characteristic in the findings in the individual cases. The miliary or nodular lesions are due to aggregations of sarcoids in the lung parenchyma. The linear lesions may be due to sarcoid lymphangitis, to lymphedema, to congestion or occasionally to fibrotic changes.

Combined pulmonary lesions and lymphadenopathy were present in 13 cases. Hilal or mediastinal lymphadenopathy or both without pulmonary involvement was present in 11 cases. In the latter group 6 patients showed bilateral hilal, plus right paratracheal adenopathy 3 showed hilal adenopathy alone 1 paratracheal adenopathy alone and 1 hilal plus left paratracheal adenopathy. Of 3 patients without chest findings, 1 died in a short time of generalized sarcoidosis and the other developed hilal adenopathy after a 3 weeks period of observation.

The lymph node enlargement seemed to follow a rather set pattern in approximately 62 per cent of the patients in these last two groups (13 of 21). This pattern has not previously been described and consists of bilateral fairly symmetrical hilar enlargement combined with right paratracheal enlargement. The combination is called the sarcoid type of adenopathy.

The nature of the "primary" or "first re-infection type" sarcoid lesion in the lung has not been established. Some have stated that the early pulmonary lesion is a diffuse millary one however in 2 definite and 12 probable early cases the author found the following distribution: disseminated millary lesions 1; nodular lesions (diffuse or localized) 3; nodular or linear parenchymal densities with adenopathy 6; adenopathy alone 4. The impression is that there is more chance of the primary pulmonary manifestation of sarcoidosis being one of combined parenchymal densities plus lymphadenopathy than there is of its being purely a millary parenchymal process.

The diagnosis of sarcoidosis remains largely a histological procedure though certain roentgen findings, combined with clinical information, are very suggestive. These are mentioned in the following order of frequency: (1) bilateral hilar and right paratracheal adenopathy with or without associated pulmonary infiltration or nodular densities; (2) widely disseminated pulmonary millary or nodular densities without calcification in a person clinically well; (3) massive enlarged hilar nodes (potato nodes) in an apparently well person. The presence of associated lesions in the peripheral nodes, skin and uveal tract is quite helpful in the diagnosis. Classical cystic changes in the bones usually occur in about 10 per cent of the cases, and an additional 10 per cent show coarse trabeculae with cortical thinning due to infiltration of the marrow with hard tubercles and fibrous tissue. Short case histories are included.

R. B. LEWIS, M.D.

Sosman, Merrill C.: Venous Catheterization of the Heart. I. Indications, Techniques, and Errors. *Radiology* 1947 48 441.

Catheterization of the right heart is most useful in the study of hemodynamics, both in establishing the normals for physiological variations and the changes in varied forms of heart failure, cardiopulmonary disease and shock. It is valuable also in helping to establish the diagnosis more accurately in congenital heart disease. In addition the method has been used in the study of cerebral renal and hepatic physiology in health and disease by the collection of samples of blood from the jugular renal or hepatic veins as desired.

The technique of performing venous catheterization of the heart has already been published. At present a single lumen catheter size 9 French made of woven silk, and radiopaque with the orifice at the tip is used. It is from 100 to 125 cm. in length flexible, and yet stiff enough so that it can be rotated by twisting the exposed end without buckling. It should

have a slight curve or bend near the tip. Under strict aseptic precautions and novocaine anesthesia an incision is made through the skin over the median basilic vein in either the right or left antecubital space. The catheter is then threaded into the vein advanced under fluoroscopic guidance and aimed at the desired area by pushing and twisting the proximal end. The catheter is thus passed upward into the axillary vein, the superior vena cava, and into the right auricle. From here the catheter is manipulated into the right ventricle. From the right ventricle the catheter may be introduced through the pulmonary valve into the right or left pulmonary artery as desired. In patients with congenital heart disease 2 or 3 samples of blood are withdrawn through the catheter from the pulmonary artery from the right ventricle, from the right auricle and from the superior vena cava, and spot films are taken of the tip of the catheter in various positions numbered to correspond to the numbered samples of blood. The samples are analyzed for their oxygen content. Blood pressure readings in the various chambers are taken.

Failure to secure adequate or reliable data from this test has been infrequent, only 13 examinations of 100 being unsatisfactory.

FRANK L. HUMBY, M.D.

Holt, John F.: Epipericardial Fat Shadows in Differential Diagnosis. *Radiology* 1947 48 473.

The roentgen visualization of fat deposits along the left border of the heart at times completely obliterating the cardiophrenic angle in adipose persons is not uncommon. There are a few articles in the literature pointing to the fact that similar roentgen shadows may be present along the right border of the heart.

The author, after reviewing 56,000 routine admission 35 mm. photofluorograms made at the University Hospital of Ann Arbor, Michigan, found that the incidence of right median base shadows constituted 0.6 per cent of the total. From this group he selected 14 cases which he briefly describes in the text, using a typical roentgenogram for illustration in 8 cases.

The shadows of epipericardial fat deposits may show considerable variation in size and shape but in general they appear roughly triangular or ovoid with the outer margin well defined and somewhat convex. Fat, as a rule, is less dense than other soft tissues but against a background of aerated lung the difference in density is lost to a considerable degree. The list of lesions from which a differentiation must be made includes mediastinal tumors, bronchogenic neoplasms, metastatic tumors, tuberculous aortic aneurysm and other anomalies of the diaphragm, diaphragmatic tumor, paraspinal effusion following splanchnicectomy, rotoscoliosis and even a large hypertrophic osteophyte.

Careful examination by several methods is necessary. Frontal and lateral roentgenograms of regulation size should always be made and supplemented if necessary by fluoroscopy and roentgenograms in

oblique projections. In the lateral view the fat pad is invariably located at the anterior costophrenic sulcus, and the extremities of its smoothly marginated, bow-shaped posterior border appear to fuse gently with the anterior chest wall. Bronchoscopy and bronchography may be useful at times. If herniation of the diaphragm is suspected a complete examination of the gastrointestinal tract including a barium enema, should be made.

If the diagnosis remains inconclusive periodical checkup roentgenograms are advisable.

T LECUTIA M.D.

Glenn, John C., Jr., and Baylin, George J.: *The Roentgen Findings in Acute Pancreatitis. Am J Roentg* 194 57 604.

Acute pancreatitis is by no means rare yet the clinical diagnosis is made rather infrequently.

A review of the literature shows that the condition occurs preponderantly in males (70 per cent) compared to 59 per cent in females) between the ages of 30 to 60 years and that it is encountered mostly in the obese heavy eaters and drinkers.

The most important etiologic factors are summarized as follows:

1. *Infectious origin.* (a) Through the lymphatics (b) through the blood stream (c) through the pancreatic or bile ducts (d) by direct extension from the kidney gall bladder etc. (e) activation of bacteria and toxins in normal glands (f) as a complication in mumps typhoid scarlet fever diphtheria and other diseases.

2. *Noninfectious origin.* (a) Reflux into the pancreatic ducts of (1) bile due to stone in the ampulla of Vater, spasm of sphincter of Oddi, edema of the ampulla of Vater or diverticulum of the duodenum (2) duodenal contents (b) erosion of peptic ulcer (c) obstruction of pancreatic ducts due to (1) epithelial metaplasia of duct epithelium (2) tumors, worms, calculi (d) trauma (1) surgical, (2) anesthesia, (3) accident (e) vascular accidents (1) embolus, (2) thrombosis (3) cardiac decompensation with vascular congestion (f) autolysis of pancreas.

3. *Chemical* (a) Arsenic, and (b) alcohol

4. *Combination of factors*

The most common etiologic factors are biliary tract diseases and alcohol. Weiner and Tennant found that in 51 individuals dying during acute alcoholic episodes, 25 showed acute pancreatic and 5 showed chronic pancreatic lesions. It has been shown that the injection of almost any material into the pancreatic ducts is capable of producing pancreatitis.

Acute pancreatitis is characterized by a sudden onset of epigastric pain which is so severe that Movnithan calls it a "formidable cata trophe," by nausea, vomiting distention and signs of collapse. However these findings are also observed in biliary tract disease perforated viscus, and intestinal obstruction, a fact which often makes differential diagnosis very difficult. The most valuable sign

pointing to acute pancreatitis is the sudden onset of severe pain commonly after a hearty meal or a drinking bout.

The most frequent laboratory findings are those resulting from the effects of dehydration. In some of the patients a high fasting blood sugar level is found. The serum amylase and lipase, and the urinary diastase determinations are, according to Whipple, Skoog, Polowe and other investigators, of certain diagnostic aid.

The authors also give a detailed description of the anatomy of the normal pancreas and discuss at length the pathology of acute pancreatitis.

The roentgen findings in acute pancreatitis are characterized by regional abnormalities induced because of the strategic anatomic relationships of the pancreas. Case and more recently Metheny, Roberts and Stranahan reported a number of roentgen changes associated with pancreatitis. The authors agree with most of the changes but they think that the stress placed on the atony of the duodenum is exaggerated. True they have found in some cases an atonic bulb filled with gas but more often there was a rather peristaltic spasm of the duodenal loop associated in some with contour changes and in others with no such changes. The authors also believe that some alteration occurs in the mucosal relief and the peristaltic function of the proximal jejunum, or the part of the colon in direct contact with the pancreas giving rise to constant areas of spasm intermingled with apparent or real dilatation and a coarsening of the fold.

The authors summarize the roentgen findings in acute pancreatitis as follows: If the head of the pancreas is enlarged the duodenal loop is widened the valvulae conniventes are flattened the inverted

"J" sign of Frostberg may be present and there may be a spasm of the duodenal loop. In addition there may be a pressure defect or a spastic area of the transverse colon and some of the small intestine may show alternate areas of spasm and dilatation. The foramen of Winslow may become sealed off, leading to a collection of fluid in the lesser omental sac with displacement of the stomach. An obstruction of the common duct may lead to enlargement of the gall bladder and liver. The neck of the pancreas is in close proximity to the bulb and pylorus and its involvement would produce distortion and displacement of these organs. The body of the pancreas is in relationship with the stomach duodenojejunal flexure, small intestine left flexure of the colon, pillars of the diaphragm, left kidney and aorta, and other blood vessels. A pressure effect on all of these organs may lead to manifold changes. Rather important findings are the fluid at the left base due to the diaphragmatic relationship and the obliteration of the left psoas and renal shadows secondary to edema or inflammation of the soft tissues. The tail of the pancreas contacts the diaphragm, splenic flexure of the colon and the spleen. Corresponding changes may occur in these organs.

It should be remembered that a duodenal diverticulum, although not particularly alarming when buried within the pancreatic substance and inflamed, may lead to pancreatic disease.

A bibliography of 34 articles is appended.

T. LEUCUTIA, M.D.

Brailsford, J. F.: Some Experiences with Bone Tumors. *Brit J Radiol.*, 1947 20 129.

The author reviews 10 cases from his files to illustrate certain pitfalls in the diagnosis of tumors of bone.

Case 1. A girl age 14 was first seen in December 1944. She complained of a tender swelling over the upper left arm which followed a severe blow 7 weeks previously. A roentgenogram revealed multiple regular periosteal accretions over the anteromedial aspect of the upper third of the humeral shaft. The compact bone was broken and irregular and the cancellous tissue was blurred. The findings were considered compatible with Ewing's sarcoma, however in view of the recent trauma the author believed that the lesion was probably inflammatory. The Wassermann reaction was positive. A course of sulfathiazole and antileptic therapy was started. Films made October 1946 showed the humeral shaft restored to normal. The author believes that the Wassermann reaction should be obtained in all bone tumors since syphilitic lesions may simulate many other pathological conditions. Multiple linear periosteal accretions may be due to syphilis, tuberculosis, bone sepsis or Ewing's sarcoma.

Case 2. A girl age 6 with a painful swelling over the right upper arm was observed for several weeks and was then discharged with a diagnosis of sarcoma with multiple metastases in the lung. The roentgenograms analyzed by the author showed marked changes in the upper half of the humeral shaft (diaphysis only) which had fractured. The disintegration of the bone and the periosteal reaction was indistinguishable from osteomyelitis but there were multiple rounded secondary lesions in the lungs which were very suggestive of sarcoma. In view of the hopelessness of any operative procedure the patient was treated with sulfathiazole in the hope that the lesion was inflammatory. The lesions progressed for 3 or 4 months then started to improve. By the end of 6 months the patient was entirely well clinically and the roentgenograms were normal. Although the diagnosis in this case was never established, the complete cure of an apparently hopeless case is remarkable.

Case 3. A young man, age 25, returned from India with the complaint of a lump in the lower left thigh. Radiographs showed an ill defined destruction of the superficial and medullary outlines of the femoral shaft at the junction of the middle and lower thirds. There were ill defined linear spicules at right angles to the cortex, arranged in a fusiform shape and some deep soft tissue swelling and multiple linear periosteal accretions along the cortex. The chest was clear. The destruction increased during the next 2 months.

X-ray therapy was given during the next 4 months. The response was excellent. Five months after therapy roentgenograms revealed a lesion of the femur which because of sharp outline appeared benign. There was no change during the next 6 months. At the end of this period there was evidence of localized extension in the shaft of the femur. Three months later there were metastatic lesions involving the fifth lumbar vertebra and pelvis. The limb was then amputated at the hip joint. The histological sections were reported as secondary carcinoma, probably of bronchial origin. The author believes that before surgery is resorted to a thorough search for possible metastases should be made particularly in areas in which the patient complains of pain.

Case 4. A boy age 14, had progressive painless enlargement of the lower half of the right thigh. The radiograph showed separation of the lower femoral epiphysis, and multiple periosteal accretions about the lower end of the shaft. There were some bone fragments and amorphous calcium deposits in the soft tissue. The clinical and radiological evidence pointed to a fracture through a sarcomatous lesion but because of paralytic deformities of both extremities, operation was postponed. The bone lesion slowly resolved finally clearing completely. This was apparently a neurotrophic lesion similar to a Charcot's joint.

Case 5. A girl, age 18, had complained of a dull pain in her left knee for 2 months, the pain being worse at night. There was no history of trauma. X ray findings showed a localized sclerosis of the medial tibial condyle which was suggestive of sarcoma. The lungs were normal. A biopsy was reported as showing cicatricial fibrous tissue and chronic inflammatory changes of the bone and synovial tissue but nothing suggestive of tumor. A roentgenogram 1 month later showed further involvement of the head of the tibia, sarcomatous in appearance. Metastatic lesions developed rapidly and the patient died. The author mentions a second case from which 2 biopsies were taken, both showing only an inflammatory change, yet the patient died 2 years after the onset. In a third roentgenographically similar case the limb was amputated promptly but the patient died within a year with pulmonary metastases.

Case 6. A patient, age 20, complained of pain in the left knee joint. Physical examination and roentgenograms were negative. Months later x ray films showed a localized osteolytic lesion at the lower end of the femur which was called an osteoclastoma. A course of x ray therapy was given. Roentgenograms immediately and 1 month after therapy showed progression of the lesion, however consolidation was apparent 3 months later and was almost complete at the end of 1 year.

Case 7. A patient, age 31, complained of pain in the knee joint. Roentgenograms indicated an early osteoclastoma. X ray therapy was given but the tumor did not respond. Subsequently the leg was amputated, and the x ray diagnosis was confirmed by histological sections.

The author has observed patient with osteoclastoma who 3 year after limb amputation have developed pulmonary metastases other patients develop metastases as long as 15 years after a positive biopsy has been reported. Simple chondromas of the extremities frequently present histological appearances which are regarded as chondrosarcoma. Chondromas of the pelvis, on the other hand, usually appear simple but metastases frequently develop.

Case 8. A male, age 58, complained of pain in the knee joint, limitation of motion and swelling on the medial aspect of the joints. The roentgenogram revealed osteoarthritic changes in the knee joint and some cortical irregularity of the medial aspect of the upper end of the tibia over which soft tissue swelling was shown. The findings suggested sarcoma and the leg was amputated. On examination the soft tissue tumor was found to be a Baker's cyst.

Case 9. A boy, age 16, complained of swelling below the knee for 1 month. There was no history of injury. The roentgenogram showed erosion of the cortex with some ill defined disintegration of the adjacent cancellous tissue. Multiple rounded opacities in the lung were interpreted as secondary sarcoma. The patient died a few weeks later. The author states it is almost inconceivable that an earlier diagnosis could have been made in this case or that prompt amputation of the leg would have appreciably affected the course.

Case 10. A male, age 60, complained of pain in the region of the right shoulder. Physiotherapy did not relieve the pain. A roentgenogram revealed some arthritic changes but no other abnormalities. Because of persistence of the pain in spite of more physiotherapy, a second roentgenogram was made 4 months later. This revealed almost complete disintegration of the scapula by secondary carcinoma. The latent negative period of metastatic malignancy may extend into months. Persistence of pain is an indication for periodic roentgenogram, especially in patients past middle life. The author believes that the possibility of a metastatic lesion should be considered of any bone lesion occurring after the second decade and, if surgery is contemplated, a search should be made for other metastatic lesions however once a metastatic lesion has been established there is nothing to be gained by an extensive investigation to locate the primary lesion.

The diagnosis of bone tumors is dependent on the radiographic and clinical evidence. Biopsies when the above mentioned evidence is indefinite are likewise equally indefinite. Repeated observations extending over weeks or months are preferred. Since the author has never seen a cure resulting from prompt amputation of a limb showing typical roentgen evidence of osteogenic sarcoma, he believes there is nothing to be gained by undue haste and precipitate amputations.

R. B. LEWIS, M.D.

Clarf, L. H.: Keratosis of the Larynx. *J. Am. M. Ass.* 1946, 133: 813

Keratosis of the larynx exists in all grades from simple diffuse hyperplasia to papillomatous masses which fill the larynx. Carcinomatous ulceration may be seen. Other terms for the condition are hyperkeratosis, leukoplakia, and pachyderma laryngis. It is usually a localized benign hyperplasia of epithelium which does not invade the inflamed submucosa. Smoking seems to be commonly associated, and vitamin A deficiency may be a contributing factor. The disease is especially important because of the occurrence in some patients of "precancerous" lesions or true carcinoma. The principal symptom is huskiness or hoarseness of the voice. Patients without evidence of cancer should be observed, smoking stopped and vitamin therapy instituted. Surgical removal of keratotic material may be required. More radical surgery is demanded by extensive keratosis or by cancer.

CURTIS H. TAYLOR, M.D.

Sprindrich, J. and Hladky R.: The Treatment of Carcinoma of the Larynx. A Comparison of the Results of Surgery and of Irradiation Therapy by the Method of Coutard (*Účinná rakoviny hrtanu. Srovnání výsledků léčebné operativní a ozařovací metody Coutardovy*). *Lék. listy* 1946, 1: 440.

In 140 cases of cancer of the larynx, treated by all forms of irradiation therapy and by surgery from 1935 to the end of 1944 in Brno, there were 49 cures (35 per cent). Surgery cured 71.4 per cent of the pa-

tients, and irradiation cured 19.3 per cent, including both operable and inoperable cases. Since 1939 when Coutard's method began to be used exclusively the percentage of cures by irradiation therapy rose to 25 per cent. However when the percentage of cures for the method of Coutard is calculated on the basis of operable cases it rises to about 80 per cent.

These experiences and a study of the literature convince the authors that irradiation therapy is of great value in the treatment of cancer of the larynx. In 1935 they treated only inoperable cases with irradiation methods, while in 1945 they treated the intralaryngeal growths by the Coutard method, reserving the cases in which the new growth had penetrated the cartilage for laryngeal fissure. It is true that intralaryngeal surgery is still used, but irradiation therapy is gaining more and more favor especially because of the better functional results. Of the irradiation methods, that of Coutard has become the treatment of choice. However the authors believe from their experience that when the tumor has passed the cartilage, it is no longer curable by irradiation methods.

An improvement in results can, in the authors' opinion, still be achieved by a closer co-operation of all the services—laryngological, surgical and irradiation, by making an early diagnosis, by more exactly placing the indications in the individual patient, and by perfecting all methods of treatment to the point where the results attained will no longer be a matter of chance, but a matter of certainty.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Adair, Norman; Cooper, George, Jr.; and Patterson, William M. Familial Osseous Atrophy. *Radiology* 1947 48 509.

A condition known as familial osseous atrophy first described by Smith in 1934 is discussed. One case is presented. The patient, a white male, age 25 was first seen by the authors in 1941. The condition began about 3 years prior to examination with bilateral plantar calluses which sloughed and formed large ulcers that would heal and break down in turn with rest and ambulation.

The patient's familial history showed similar conditions in a paternal grandfather, a father and 2 paternal uncles.

Clinically the patient had cold clammy feet with swelling and tenderness of the distal two-thirds. There were draining ulcers under the inner spaces between the distal ends of the first and second metatarsals on each foot. Neurological examination showed loss of heat and cold sensations over the toes and hyperactive reflexes of both lower extremities. Pulsations of the posterior tibial and dorsalis pedis arteries were strong and full in both feet. There was moderate unguinal lymphadenopathy and microscopic examination showed this to be chronic lymphadenitis.

After 4 years without treatment the ulcers were found to be larger and the feet considerably shortened.

Radiological examination at first showed necrosis of the distal 4 cm. of the right first metatarsal bone. The margin of the distal end of the remaining portion of the shaft was irregular with multiple small amorphous sequestra about the first metatarsophalangeal joint. There was no periosteal reaction. The cortex was moderately decreased in density and the surface was slightly irregular. The only loss of trabeculation was in the inferior and distal centimeter where the bone appeared amorphous. The phalanges showed moderate atrophy and decrease in circumference. After 4 years there was complete absence of the metatarsal bones except for the proximal portions which were atrophied. The distal ends of the naviculars, cuboids and cuneiforms were absent. The remaining bones of the feet were moderately atrophic. The rest of the skeleton was normal.

The x-ray appearance was not that of pyogenic infection. Smears, cultures, biopsy studies and blood and spinal fluid examinations ruled out tuberculosis, fungus, leprosy and syphilis. Blood calciums were normal. The skin sensitivity to cold and heat showed no definite outline of nervous innervation.

In a group of similar cases reported by Tocantins and Reimann in 1939 both males and females were

involved. The etiology of the disease is unknown and the clinical course and radiological findings are characteristic. It progresses after onset to finally cripple the victim. No deaths have been known from this malady. W. FOSTER MONTGOMERY, M.D.

Curtis, George M. and Fertman, M. Boen: Blood Iodine Studies; The Blood Iodine in Nonthyroid Disease. *Arch. Surg.* 1947 54 541

The authors present their findings in a study of the blood iodine level of representative patients with 115 different nonthyroid diseases. They have found that these nonthyroid diseases affect the basal metabolic rate less characteristically than thyroid disease and even more seldom cause any change in the blood iodine. Those deviations of blood iodine level which were found were practically always increases and were not necessarily accompanied by an abnormal basal metabolic rate.

In 11 patients with chronic cholecystitis 9 of whom also had cholelithiasis the average blood iodine level was significantly raised approximating that found in patients with toxic goiter but without change in basal metabolic rate. The 2 patients in whom no biliary tract calculi were present had the lowest values in the group. The single patient with obstruction of the common duct had a high blood iodine, but not the highest of the group. These elevations have particular interest in the light of the role the liver is thought to play in iodine metabolism.

In a group of 14 patients with essential hypertension and hypertensive heart disease both the blood iodine level as determined by the dry ash method and the basal metabolic rate were significantly elevated. In a subsequent group of 14 other hypertensive patients in whom the blood iodine level was determined by the more recent chromium trioxide oxidation method there was no truly significant elevation. Of 16 patients said to have hypertension without cardiac disease, only 5 had elevations of the blood iodine, with slightly elevated basal metabolic rates. Among nonhypertensive cardinals there was no elevation of the blood iodine, even when congestive failure was present. Renal disease does not appear to influence blood iodine levels, at least not until some degree of renal failure has occurred. The values in patients having blood dyscrasias and degenerative diseases demonstrated individual variations but no significant deviation common to all members of a particular category. However of 3 patients with lymphatic leukemia, 2 did show a marked elevation of blood iodine accompanied by an increased basal metabolic rate.

Among the other types of diseases studied, in the nonthyroid endocrine disturbances and certain infectious diseases there were interesting but inconclusive deviations from the normal both increases and decreases. Several skin diseases, each repre-

sented by a single patient, showed significant increases. There was no particular abnormality of the blood iodine levels found in psychic disorders, myelogenous leukemia, or neoplastic diseases (both benign and malignant) of extrahepatic and extra-thyroid origin.

The article contains 4 tables elaborating the findings in all the nonthyroid diseases studied. The pertinent literature on blood iodine studies is reviewed.

BENJAMIN F. LOCKABURY, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Lamb, John H.; Lala, Everett S.; and Jones, Phyllis E.: Actinomycosis. *J. Am. M. Ass.* 1947 734 351

Actinomycosis may appear near any body cavity, but it is most common about the mouth and there it may be primary but usually it is secondary. It is not regional and is found over the entire world.

The exact nature of the causative organism has been disputed. An aerobic actinomycete was first isolated from submaxillary lesions. Later an anaerobic pleomorphic organism, which changed from a threadlike fungus to segmented bacilli, was found in carious teeth, root canals of teeth and in tonsils. It has been theorized that the fungus invades tissue previously altered by pyogenic organisms.

The 'straw chewing theory' is abandoned because there is no evidence that the organism is capable of maintaining growth on vegetable matter.

Primary cutaneous actinomycosis applies to those cases in which the infection does not spread from a neighboring mucous membrane or from a systemic infection. Diagnosis is difficult without biopsy and aerobic and anaerobic cultures.

The onset of the disease is usually insidious. There is a history of chronic periodontitis, with swelling of the soft tissues, and occasional pain. The fungus in company with bacteria migrates directly to the bone and soft tissue. After a time the person becomes hypersensitive to the actinomycetes, and actinomycosis results as an allergic manifestation to a common parasitic inhabitant of the mouth, teeth and tonsils. Most of the authors' cases of acute actinomycosis have been preceded by the extraction of infected or pulpless teeth.

Diagnostic features are dark red discoloration of the skin, projection of the lesion and the surrounding skin, multiple nodules with the formation of ridges and furrows in the creases of the skin on the neck, induration, and multiple sinuses with macroscopic and microscopic granules of actinomycetes in the pus.

All the sulfonamides except sulfapyridine are recommended with sulfadiazine favored. Eight

grams are given the first day, 6 gm. daily for the next 4 days, 4 gm. daily for the next several weeks, and then 2 to 3 gm. for the following 3 months. Liver extract—10 units three times per week—is given with sulfa therapy to avoid leucopenia and agranulocytosis.

Penicillin—1,000,000 units daily for 10 day periods—has been given with success. It is recommended that three such courses be given.

Röntgen therapy with a total of 1,500 to 2,200 röntgens has been successful and is used as an adjunct to sulfadiazine.

The authors do not favor radical surgical excision in acute cases because of the recurrence in the surgical scar. Surgery may be indicated to remove sequestra after the infection has been controlled by röntgen ray therapy and drugs.

DANIEL ROUX, M.D.

DUCTLESS GLANDS

Langeron, L.; Glard, P.; and Volf, V.: Cushing's Syndrome—Anatomoclinical Observation (Staladie de Cushing. Observation anatomoclinique). *L. m. caduc.*, Jan. 1947 811

The authors had the opportunity to follow up a case of Cushing's syndrome for a period of several years and to obtain a detailed postmortem examination. Contradictory observations by recent investigators have raised considerable doubt as to the true etiology of the syndrome.

The symptoms and signs of the patient observed were divided into two phases. The first phase extended from age 20 to age 30 years and was marked by hypophyseal symptoms of amenorrhea and signs of obesity, cutaneous changes, and disturbances of the glucose metabolism. There were isolated changes attributable to the parathyroid glands, chiefly generalized osteoporosis, trabecular fractures, and even vertebral collapse. The suprarenal signs were only discreet and moderate hirsutism.

The second phase of the illness extended from age 30 to death at age 33 and was characterized by the rapid development of vascular complications terminating in death from renal failure and pulmonary edema.

At autopsy no adenoma of the pituitary was found. There was an excessive number of basophilic cells and of very large cells with degenerated and hyalinized cytoplasm. There were no lesions of the suprarenal glands or ovaries. The kidneys exhibited hyalinized sclerosis of the arterioles and early interstitial sclerosis.

The authors conclude that the amenorrhea and the osteoporotic changes were of hypophyseal rather than ovarian and parathyroid origin.

Blood pressure. Immediate decrease in blood pressure seen at conclusion of cyclopropane anesthesia cyclopropane shock, 89 physiological studies in congenital heart disease results of preoperative studies in patients with tetralogy of Fallot, 242

Blood transfusion. Plasmal S-25 79 replacement of blood, 189 influence of sex of donors and recipients on frequency and gravity of reactions from 399 fatality in blood donor case report with review of literature, 399, importance of aseptic technique and fallaciousness of chemical bacteriostatics in banking for and plasma preserving 498, peritoneal irrigation for uremia following incompatible report of case, 499 method of rapid, into femoral vessels in patients without adequate peripheral superficial veins, 505 distribution and use of human whole blood in Pacific war 586 elliptocyte, as method in studies on destruction volume, and peritoneal resorption of blood, 587 homologous serum hepatitis following 587

Blood vessels. Carotid sinus thrombophlebitis, report on 6 consecutive recoveries, 9 effects of vascular lesions on peripheral nerve lesions, 19, coarctation of aorta, 26 mesenteric vascular occlusion 35 gastric ulcers produced experimentally by vascular ligation, 33 pathogenesis of cardiovascular and renal changes which usually accompany malignant hypertension, 19, thrombophlebitis on medical service of a general hospital, 77 use of shunt or by-pass operations in treatment of certain circulatory disorders including portal hypertension and pulmonary stenosis, 77 peripheral vascular sclerosis, 78 new experiments pertaining to pulmonary embolism, 134 some aspects of Volkmann's ischemic contracture, 176 spontaneous rupture of subclavian artery 188 problems in arterial surgery, 188, arteriography by injection and automatic taking of negatives, 292 war experiences with noninvasive technique of anastomosis in primary arterial injuries, 293 mechanism of hemostasis, 294 disease processes versus disease pictures in interpretation of retinal vascular lesions, 328, rare lesion from flare gun 398 successful suture of abdominal aorta for arteriovenous fistula, 398 cerebral thromboangiitis obliterans, 453 technique of creation of artificial ductus arteriosus in treatment of pulmonary stenosis, 461 fluorescent wheel test for collateral circulation in preoperative evaluation of patients with aneurysms and arteriovenous fistulas, 498 extremity refrigeration without tourniquet ligation in cases of acute arterial deficit, 505 method of rapid transfusion into femoral vessels in patients without adequate peripheral superficial veins, 505 venous catheterization of heart results, interpretations and value 514 Ménière's syndrome evidences for vascular mechanism, 534 tetraethylammonium as adjunct in treatment of peripheral vascular disease and other painful states, 585 multiple retrograde saphenous vein ligation and phlebectomy with aid of malleable intraluminal guide, 585

Body. Sudden shifts of fluids in human, 98

Bone. Observations concerning Ewing's tumor seen in army general hospital, 65 multiple myeloma, 66 skin grafting in treatment of osteomyelitic war wounds, 67 arrest of growth of epiphyses, 68, marble disease of study of osteogenesis, 73 discussion on primary malignant tumors of (symposium) 95 chronic proliferative osteomyelitis of skull, 121 eosinophilic granuloma of frontal, 121 urinary lithiasis following osseous wounds of war 169 multiple exostoses, 174 treatment of multiple myeloma, 175; survival in sarcoma of, 175, grafting of pseudarthroses and recent fractures of tibia, 182 psychosomatic approach to orthopedic surgery 186 newer pathologic and physiological concepts of anterior poliomyelitis and their clinical interpretation, 186 treatment of multiple metastases in, with widespread osteolysis of vertebrae or ribs by radiotherapy in massive doses combined with total teletherapy disappearance of radiological and clinical signs, 203 thoracobrachial nevus with osteohypertrophy of entire upper extremity. Parkes-Weber syndrome, 203 studies on experimental osteogenesis by homotransplantation of living mucosa, 207 osteogenesis of autotransplants of living mucosa, 208 malignant adenoma of thyroid with secondary metastases to, 234 osteopetrosis and cancer of duodenum, 249 von Recklinghausen's generalized osteitis fibrosa cystica and epithelioma of breast difficulties of diagnosis, 281 roentgenologic considerations of rare osteoarthropathic syndrome, 282 blood supply of 283, vitamin A deficiency and excess in relation to skeletal growth, 289 Jaffe Lichtenstein's disease cystic osteofibromatosis, 388, changing concept of myeloma of 388 treatment of chronic osteomyelitis with streptomycin 390 histopathological aspects of Koehler's disease of metatarsals, 395 normal and pathologic growth of in light of development of cartilaginous foci in chondrodysplasia, 487, dysplasia epiphysealis multiplex, 487 pleonosteosis (Leri's disease) 488 sarcoma in abnormal, 488 Mommensen's osteotomy as palliative operation on hip, 489 value of external skeletal fixation in elective orthopedic surgery 491 stimulation of longitudinal growth in tibia by elevation of diaphyseal periosteum, 497 Milkman's syndrome and spontaneous fissures of skeleton 578 osteoid osteoma associated with changes in adjacent joint report of 2 cases, 579 course of paralyzes in patients with poliomyelitis, 580 evaluation of cortical and cancellous, as grafting material clinical and experimental study, 583 some experiences with tumors of 607 familial atrophy of 609

Bones. Painful, nonsuppurative, localized sclerosis of long, with report of 2 cases, 174 management of extensive complete defects in long, 390

Bowel. Obstruction of, in newborn, 149

Brachial plexus. Treatment of injuries of 541

Brain. Cerebral blast syndrome in combat soldiers, 17; war wounds of ventricles of, 17 lack of cerebral effects of d-tubocurarine, 89 contribution to study of lipoma of corpus callosum, 129 physical rehabilitation of patients with injuries of 237 too cases of tuberculoma of central nervous system, 237 second day encephalography with particular reference to size of ventricles, 338 penicillin in treatment of craniocerebral injuries of war 338, traumatic meningitis and ventriculitis, 340 cerebral thromboangiitis obliterans, 452 surgical treatment of hydrocephalus, 452 pneumoencephalogram of cerebellar atrophy 512 streptomycin in surgical infections, otitis externa, otitis media, mastoiditis, brain abscess and meningitis, 535 wounds of head,

- 540 symptomatology of subdural hematoma in infants and adults, comparative study with particular reference to ocular signs; observation concerning pathogenesis of subdural hematoma, 549
- Breast.** Effect of estrogenic hormone on advanced carcinoma of female, 21 path of gene action in tumor development in mice, 99 tumors of in mice following transplantation of tumor of, 99 mammary tumors in male mice implanted with estrogen-cholesterol pellets, 100 plasma cell mastitis, 24 von Recklinghausen's generalized osteitis fibrosa cystica and epithelioma of difficulties of diagnosis, 283 treatment of abscesses of, with penicillin, 343 carcinoma of, 457 penicillin and acute puerperal mastitis, 478 histological notes on fibrocystic mastopathy before and after treatment with male sexual hormone, 545 considerations on late results of postoperative roentgen therapy of cancer of, 546
- Breath births.** Results of treatment of at Midwifery School at Helsinki during years 1934 to 1944, 567
- Brester tumors of ovary** 56
- Bronchiectasis.** 457 genesis of unappreciated bronchiectatic force, 23 surgical treatment of, 3 intrabronchial administration of penicillin and sulfonamide, 345 bilateral lobectomy to bilateral, 547
- Bronchography.** Discussion of subject of alveolar filling in, 412

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Fabing, H. D.: Cerebral Blast Syndrome in Combat Soldiers. *Arch. New Psychol.*, Chic., 1947 57 14.

The author presents a detailed study of 80 cases of blast injury which occurred in combat troops. The unconsciousness following such explosions was characterized by retrograde amnesia for the blast and a period of anterograde unconsciousness for a period of about one hour. This unconsciousness was usually marked by aimless dissociated behavior. The chief complaints following recovery of consciousness were diffuse anxiety symptoms and a nonspecific head ache. There were no constant physical or neurological abnormalities. Spinal fluid studies failed to reveal any deviations from the normal except in a few patients (2.5 per cent) in whom intrathecal bleeding had occurred.

Various types of therapy were attempted. Memory during the unconscious period was found to be intact under chemical hypnosis. It was noted that if a conscious recall of this material could be accomplished, the blast injury symptoms were ameliorated or entirely removed. This was best done by the use of intravenous sodium pentothal in developing and existing amnesic experiences. The patient was then suddenly awakened by the intravenous injection of coramine, and the amnesic details were discussed. This method proved of definite therapeutic value in 90 per cent of the patients.

Several detailed case reports are given as well as a general discussion of the literature pertinent to blast injury. C. FREDERICK KITTLE, M.D.

Pitts, W. R.: War Wounds of the Ventricles of the Brain. *A. J. Surg.* 1947 73 3

This report deals with penetrating wounds of the cerebral ventricular system as seen and treated in an evacuation hospital. In this hospital which received 10,455 casualties there were 108 penetrating wounds of the brain and 16 of these involved the ventricles. Of the latter group 3 led to death without any surgical procedure. 13 underwent surgery.

The 3 patients who died without surgical treatment presented deep coma, rapid stertorous respiration, rapid pulse, wide pulse pressure, and unilateral pupillary dilatation. Decerebrate extensor spasm was present in 2 cases and flaccid in 1 case. There were large intraventricular hematomas in 2 cases.

Of the group of 13 patients who lived long enough to undergo surgery all were unconscious immediately and remained so for from 30 minutes to 5 days. Nine showed a moderately widened pulse pressure. Bradycardia was present in only 2, both of whom had large intraventricular hematomas, a wide pulse pressure, and a tight brain. Localizing neurological signs were of no aid in diagnosing involvement of

the ventricles. Only in 1 case was there sufficient cerebrospinal fluid loss to implicate the ventricles. In 6 cases it was possible to diagnose penetration of the ventricles by the x ray findings and location of the wounds.

The operations were done under local anesthesia, in some cases supplemented with pentothal. All patients received morphine preoperatively. At operation there was a large variety of findings. No ventricles contained metallic foreign bodies but some contained bone fragments. There was extensive damage to gray and white matter and in 1 case the corpus callosum was damaged. Damaged tissue and foreign material were removed along the course of the projectile. Irrigation was kept to a minimum so that blood clots and foreign matter would not be washed into inaccessible regions of the ventricles. Complete hemostasis was obtained. Living fascial or peritoneal grafts were used in the closure of most of the cases. Just prior to closure of the dura, some form of bacteriostatic agent was used locally—either penicillin or sulfanilamide. Some patients were given sulfadiazine and penicillin systemically and some received penicillin intrathecally.

There were 2 deaths among the 13 patients, a mortality of 15.4 per cent. The mortality in brain wounds when the ventricles were spared was 6.7 per cent. Intracranial infection was not a factor in any of the deaths. DANIEL RUGZ, M.D.

Werthelmer, P. and Barrié, J.: Cranioplasty with Free Osteoperiosteal Grafts. Observation of 11 Cases. (*La cranioplastie par greffons ostéo-périostaux libres, à propos de 11 observations*) *J. chir.* Par 1946 62 431

Interest in cranioplasty for the repair of large cranial defects always increases during the time of war. Such was the case during the first World War as well as again after the recent war but between these two periods interest in cranioplasty lagged. The authors have not had the advantage of using tantalum but they are well aware of its wide and successful use in the hands of American neurological surgeons during the last war and in the months succeeding it.

They have found a simple method of autogenous bone grafting to be useful. Although it is not a new procedure either in France or America, it seems to be an entirely feasible and effective form of closing certain types of cranial defects. They used it in 11 cases. They turn down a generous scalp flap about the cranial defect, making sure that the flap has a wide and well vascularized pedicle. Ample normal bone and periosteum about the defect are exposed. The underlying brain and dura mater may then be inspected, and the dura mater freed from the edges of the bone defect, may be repaired with a fascial graft if that is necessary. With a chisel small mosaics of bone are removed from the outer table of the surrounding nor-

mal calvarium. These pieces of bone are placed free upon the exposed dura mater but they do not necessarily cover the dura completely. The scalp flap is then carefully replaced and sutured in two layers without drainage.

The authors feel that in 9 of their 11 patients they have had definite success. They believe they have seen such complaints as headache, vertigo and mental changes improve and disappear after cranioplasty. Follow-up roentgenological studies of the repaired defects show that the grafts melt away into a general sheetlike mass of ossification. Their method of cranioplasty is obviously a less expensive one than that which requires the use of tantalum or silver plates.

JOMY MANN, M.D.

Estells, J.: Surgical Treatment of Facial Paralysis by Resection of Upper Cervical Sympathetic Ganglion. (Tratamiento quirúrgico de la parálisis facial y resección del ganglio cervical superior del simpático) *Rev. esp. cir.* 1945 1: 143.

For cosmetic reasons facial paralysis may demand a corrective operation especially in young women. Imperfect protection of the eyeball caused by lagophthalmos may also require an operation. Only in facial paralysis of the peripheral type is an operation justified. It goes without saying that only permanent changes form an indication for operation because in many instances the paralysis recedes in the course of time. Therefore, tests with the faradic current and an examination of the patient under anesthesia are imperative. Absence of response to the electric current indicates an irreparable anatomic interruption of the nerve. Absence of response to a galvanic current indicates definite muscular degeneration and contraindicates surgical treatment because the muscles have lost their contractility.

Three groups of operations are at the disposal of the surgeon: (1) restoration of the continuity of the nerve trunk by decompression or direct suture of the nerve, (2) re-establishment of the lost motor function by utilization of the activity of intact muscles by myoplastic procedures or neuroanastomosis, and (3) resection of the upper cervical ganglion of the sympathetic system. The first two groups of operations have a limited field of usefulness and their results are not infrequently disappointing.

The technique of resection of the upper cervical ganglion is much simpler than that of resection of the stellar ganglion. The author uses the retromastoid approach. The ganglion is easily accessible upon the prevertebral aponeurosis at the level of the transverse apophysis of the second or third cervical vertebra. The retromastoid route is preferred to the pre-mastoid approach by the author because the scar is less visible and because, contrary to the prevailing opinion, the exposure of the ganglion is better. The skin through the skin is made along the upper two-thirds of the posterior border of the sternocleidomastoid muscle.

In a 54 year old woman who developed a facial paralysis of the peripheral type following a skull frac-

ture, the lagophthalmos disappeared completely following the operation and the facial muscles recuperated. The correction of lagophthalmos may be attributed to the postoperative contracture of Horner's muscle. The effect on the facial muscles may be ascribed to vasomotor and trophic modifications caused by the sympathectomy. In addition to it, compensatory kinetic mechanism may play a role.

The author concludes that a resection of the upper cervical ganglion is indicated whenever facial paralysis is permanent and a direct suture or plastic restoration of the nerve cannot be considered because the lesion is intracranial, or because the entire extracranial portion of the facial nerve is destroyed. In selected cases sympathectomy may be employed also, as a preliminary or supplemental operation.

JOSEPH K. NARAY, M.D.

SPINAL CORD AND ITS COVERINGS

Brader, M. A. B., Watkins, A. L. and Michelson, J. J.: Electromyography in the Differential Diagnosis of Ruptured Cervical Disc. *Arch. Neurol. Psychiat., Chic.*, 1946, 56: 657.

The electromyograph has been used as an instrument to detect fasciculations of muscles so fine that they are not visible to the eye. Electromyography for the detection of such fasciculations in muscles, due to lesions of the spinal cord and peripheral nerves, has been used for some time.

In the present report, 10 cases of suspected compression of the nerve roots by protruding intervertebral discs have been reviewed in the light of their electromyographic findings.

Surface electrodes were used and numerous shifts were made to find the optimum site for recording the impulses. Multiple spontaneous discharges, presenting clear cut diphasic spikes, were observed in certain muscles and not in others. The muscles showing such abnormality were then classified with regard to their nerve root innervation. By such means the suspected nerve roots were identified as having abnormal reactions.

These studies were conducted in 10 cases, and, of these 9 were operated upon. In 3 cases with suspected ruptured cervical discs, a normal electromyogram was found, and at operation no lesion was observed. In other instances, an accurate root localization was obtained by the electromyographic readings and confirmed at operation.

A differential point between recordings of impulses from muscles in cases of root compression and those in cases in which there is a degenerative process of the anterior horn cells such as progressive muscular atrophy is also discussed.

SURGERY OF THE NERVOUS SYSTEM

spinal lavage. The spinal washouts were done with the idea of preventing or combating the arachnoiditis and the formation of the meningitis.

A one-needle technique is described in which a lavage apparatus consisting of a rubber tube with man's solution is connected by a rubber tube with a clamp to a 20 c.c. syringe barrel. Irrigations are performed with amounts of 20 c.c. until the returning fluid is clear. Following the irrigation penicillin is instilled intrathecally in therapeutic doses. The effectiveness of the spinal washout is demonstrated by cell counts on the spinal fluid that is removed. The author has worked out what he calls a cerebrospinal fluid cellular clearance showing that the washouts resulted in a lowering of the cell counts of the cerebrospinal fluid and also decreased the cerebrospinal fluid pressure. As many as 6 or 7 washouts were done daily in some cases.

Untoward reactions such as herniation of the cerebellar tonsils from increased intracranial pressure are discussed and the author believes that the danger of herniation in uncomplicated meningitis has been unduly exaggerated. Headache was obviated by warming the irrigating fluid to body temperature.

In 2 of the 8 cases reported the patient died of the meningitis, another died of other causes. In the 5 cases in which the patient recovered, no mention is made of any sequelae. The author concludes by stating, "Apart from clearing pus and organisms and restoring osmosis to normal the irrigating fluid may break up commencing adhesions, and the cerebrospinal fluid pressure is kept down."

HOWARD H. LAMBER, M.D.

PERIPHERAL NERVES

Wertbelmer P: Effects of Vascular Lesions on Peripheral Nerve Lesions (Effets des lésions vasculaires sur les lésions nerveuses périphériques). *Lyon chir.*, 1946 41 385

In this article the author stresses the neurological sequelae of vascular injuries and emphasizes the importance of the blood circulation in nerve trunks. Four cases are discussed in which peripheral nerve lesions are associated with traumatic vascular lesions. The first patient had received a gunshot injury in the left subclavicular region with fracture of a complete plexus at the point of exit and presented a complete paralysis of the lower brachial plexus. Electrophysiological tests showed diminished excitability but no reaction of degeneration in the muscles of the hand and anterior portion of the forearm and massive atrophy of the entire extremity including the intrinsic hand muscles. At operation the nerve trunks were found to be intact but the axillary artery showed a traumatic obliteration. An arterectomy was performed. The patient's condition improved greatly but a year later he continued to show the signs of a median nerve palsy.

The second patient presented a high radial nerve paralysis due to a gunshot injury of the axilla. The operation disclosed intact nerve trunks and an aneurysm of the axillary artery which was resected. Ten months later the patient showed a residual paralysis of the common extensors of the fingers and of the extensors and abductor of the thumb.

The last 2 cases presented definite caualgic symptoms with paralysis and sensory disturbances, one in the right upper extremity and the other in the left lower extremity. At operation adherence of the brachial artery to the median nerve and complete occlusion of the femoral artery were found, respectively. Following periarterial sympathectomies the caualgic symptoms disappeared and the motor disturbances receded gradually.

Peripheral nerve lesions attributed to primary vascular lesions and ischemia need careful investigation and study. The evaluation of the neurologic signs is often very difficult in the presence of a nerve lesion associated with vascular disturbances. Very little is known about the blood circulation of the nerves, although it has been shown by peripheral nerves in Seddon in a recent report that peripheral proliferative degenerative and mesodermal necrosis, in purely ischemic changes, and even complete necrosis in their blood supply mic lesions due to disturbances in their blood supply.

GEORGE PERRET, M.D.

SYMPATHETIC NERVES

Lahorda, F. M.: Sympathectomy and Hydronephrosis. Principles and Indications (Explantation e hidronefros. Fundamentos e indicaciones). *Rev. esp. cir.*, 1946, 3 23

The neurosurgical treatment of dilatation of the urinary excretory ducts should be confined to cases of functional or idiopathic dilatation in which the action of the sympathetic nervous system appears disturbed.

All 10 patients operated on by the author showed painful phenomena and had considerable amelioration of their symptoms or complete recovery after the operation.

A temporary disappearance of symptoms may be obtained by the injection of an anesthetic into the sympathetic system but permanent results can be expected only from an operative procedure such as denervation of the renal pedicle, sympathectomy, extirpation of the splanchnic ganglion of the splanchnic removal of the splanchnic ganglion of the minor splanchnic nerve, or extirpation of the first sympathetic ganglion of the lumbar chain.

The relief of pain after the operative procedures is attributed by the author not to the interruption of the sensory paths but to the cessation of the spastic effect of infectious hydronephrosis, the pain in 4 cases of the sympathetic and considerable improvement in regard to the infection was noticed the latter being due to the elimination of urinary retention. A recurrence of the infection but not

- Urinary tract, Bilateral ureteral duplication with ectopic ureter 60 calculi in negro, 64 epithelial nests of mucosa of, 64 transurethral resection for postoperative retention in 377 amebic pyuria, 378 bacterial pyuria from new angle, 378 Reiter's disease followed by true infective bacterial pyuria, 379 infections of 379 infections of, 280 care of in paraplegic patients, 280 stress incontinence in female, 473 pseudophincter in neurogenic bladder 483 genitourinary conditions in infants and children 484 streptomycin in urogenital infections, 486, surgical treatment of incontinence 563 adenocarcinoma of female urethra, review 564, crossed ectopia with fusion review of literature and report of 4 cases, 570 ureteral obstruction recent advances in its embryology nosology, and surgery 571 spontaneous rupture of ureter 571 bilateral cutaneous ureterostomy 18 years after ureterocystostomy for ectrophy of bladder 571 composition of urinary calculi, 576 calculi in spinal cord injuries, 576 absorbable gauze in surgery of 577
- Urine, Effects of diets on nitrogen loss in after burns, 404
- Uterus, Cancer of at youthful age: clinico-statistical contribution 44, carcinoma of cervix during the first two decades of life, 45 corpus carcinoma, 45 etiology of onset of labor collective review 105, on conservative myomectomy 157 therapeutic possibilities in cancer of in young women 157 radiotherapy of cancer of neck of 158 review of 540 cases of genital prolapse observed at gynecologic clinic of Bahia School of Medicine since its creation until present time (1911-1946) 257 functional surgery in myoma of 257 radiotherapeutic treatment of cancer of 257 metastases of carcinoma of to central nervous system clinico-pathologic study 258, study of bacterial flora of normal and pathologic vagina and, 262 pituitary extract in inertia of in it justifiable, 266 radiation sickness in patients undergoing irradiation therapy for cancer of cervix of clinical analysis and study of therapeutic action of psychergine, 307 investigations on mucosa of biopsy material treatment, and evaluation, 372 investigations on mucosa of occurrence and significance of ectopic and cystic glands in mucosa of, 372 investigations on mucosa of on early diagnosis of metropathia haemorrhagica, 372 infectious granulomatous lesions of cervix, 373, telangiectatic granulations of urinary bladder following radiotherapy for cancer of 380 menorrhagia associated with irregular shedding of endometrium, 472 preservation of upper pelvic floor and bladder support in total hysterectomy 473 spontaneous rupture of 476 carcinoma of cervix, 562 total hysterectomy 563
- Uvea, Sarcoma of, 10 hypersensitivity and disease of 328
- Uveitis, Danger of penicillin therapy in active 443
- V**AGINA, Smear from, 159 biological aspects of secretion of during genital crises of newborn, 165 study of bacterial flora of normal and pathologic and uterus,

- 36 simultaneous bilateral ureterocenteroanastomosis according to Davalos' technique in treatment of incurable vesicovaginal fistula, 263 posterior colpotomy for diagnosis of pelvic diseases, 374 influence of estrogen upon healing of wounds of In rats, 375 cystectomy through, 383
- Vagotomy Effect of transthoracic, upon clinical course of patients with peptic ulcer 34 prevention of pyloric ligation-induced ulcers of gastric rumen of rats by transabdominal preliminary report, 353
- Vagus nerves, Resection of 246 supradiaphragmatic section of to stomach in gastrojejunal ulcer 561
- Valloclular signs diagnosis and clinical significance, 448
- Varicocoele, Due to vascular reflux: operation of Ivanisevich origin technical development, and present status, 7 operation for 385
- V ter's ampulla, Lesions of 467
- Veins, Primary thrombosis of axillary of traumatic origin 80, stratigraphic roentgenological picture of arch of large artery, 30 method of rapid transfusion into femoral vessels in patients without adequate peripheral superficial, 509 acute suppurative phlebitis complicated by septicaemia, 594
- Ventricles, Second-day encephalography with particular reference to size of 338
- Ventriculitis, Traumatic meningitis and, 340
- Vitamins, Effects of vitamin C deficiency and starvation upon toxicity of procaine, 98 vitamin A deficiency and excess in relation to skeletal growth, 289 dietary factors concerned in erythropoiesis, 499 influence of vitamin B complex on lactation, 566
- Volkemann contracture, Some aspects of, 76 syndrome of post traumatic muscular hypertonia and degenerative neuritis, 506
- Volvulus of cecum, 37
- Von Recklinghausen's disease generalized osteitis fibrosa cystica and epithelioma of breast, difficulties of diagnosis, 28
- Voorhes bag, 567
- V tra, Postpartum chorioepithelioma, 566
- W** AR, Cerebral blast syndrome in combat soldiers, 71 wounds of ventricles of brain due to, 17 surgery of wounds of abdomen due to, 431 gunshot wounds of ureter: 3 cases, with preservation of kidney in 1, 61 skin grafting in treatment of osteomyelitic wounds due to, 67 management of penetrating wounds and suppurative arthritis of knee joint in Mediterranean theater of operations, 69 thrombophlebitis on medical service of a general hospital, 77 anesthesia for thoracic surgery management in an army general hospital overseas, 88 symposium on sepsis; unrecognized battle noise trauma, 84 report of 66 lobectomies performed at Kennedy General Hospital Chest Surgical Center from 1943 to 1946 with death, 137; urinary fistulae following osseous wounds of, 69 delayed nature of wounds of 194 development of concept of antisepsis and asepsis from Lister to second World, 300, ocular injuries of 226 Immediate repair of wounds of face due to, 229 tetanus in United States Army in second world, 50 causes of death in battle casualties reaching hospitals, 37 penicillin in treatment of cranio-cerebral injuries of, 338, renal anoxia and traumatic crushing injuries of chest, 53, early treatment of maxillo-facial fractures—137 cases experiences with hospital in Casablanca, Oran and Marseille, 566 wounds of head, 540 nature of injuries of, to peripheral nerves, clinical studies of results, 24 distribution and use of human whole blood in Pacific, 586 some observations on wounds of particular reference to "stormy fermentation, 595 contribution on anaerobic wound infection, 595
- Wassermann reaction and Kahn reactions during pregnancy, 585
- Weight, Alterations of body during gestation, parturition, and puerperium, 268
- Wirming's duct, Anastomosis of use in palliative operations for cancer of head of pancreas, 566
- Wolfe technique Practical points in, of grafting, 9
- Wounds, Surgery of war of abdomen, 43 shock due to, 83; bacteriology of open, 85 chemotherapy in management of 86 war of ventricles of brain, 77 secondary damage in, due to pressure changes accompanying passage of high velocity missiles, 93 delayed nature of war 94 excision and repair of deep thermal necrosis 194 development of concept of antisepsis and asepsis from Lister to World War II, 300, immediate repair of war of face, 229 healing open phloidal, 399 cross-infection of in surgical ward during trial of use of oiled blankets, 399 bacteriologic study of burn, 404, surgical infection of in surgical ward during trial of use of oiled blankets, 399 bacteriologic study of, of pelvic viscera and their management of gunshot, 47 fibrin foam and gelfoam in late complications, 47 fibrin foam on several substances kidney 450 healing studies on several substances recommended for treatment of burns, 507 treatment of with sulfonamides, clinical and experimental histological report, 508 regeneration of, of external membrane of eye in light of new pathologic-anatomical results, 532 of head, 540, of liver 359 some observations on war: particular reference to "stormy fermentation, 595 infection of, with gram negative organisms; clinical manifestations and treatment, 597
- Wrist, Treatment of pseudarthrosis of, 69

XANTHOMAS, Solitary of synovial membrane of joints: clinical and anatomopathologic study and investigation of etiopathogenesis, 65

INTERNATIONAL ABSTRACTS OF SURGERY

pain brought 1 patient back to the hospital after a splanchnicectomy performed for an infectious bichain. In addition the last mentioned method allows the performance of supplementary operations on the kidneys, such as exploration, decapsulation and suspension.

The author did not perform a bilateral resection of the splanchnic nerves. There was no mortality attributable to the operation in his entire material.

JOSEPH K. NARAZ, M.D.

MISCELLANEOUS

Chasak, A. K., and Stout, A. P. Traumatic and Amputation Neuromas. *J. & Surg.* 1946, 53 645

The authors analyze the neuromas found in the records of the Presbyterian Hospital, New York City. Pain, anesthesia, and paralysis were the chief complaints and they occurred in the order given. The symptoms had existed for a period of from 3 months to 30 years.

The common cause for neuromas was trauma. Accidents, industrial injuries, and amputations preceded most of them. Some followed surgical procedures. The authors believe that much difficulty has occurred because of inadequate examination following injury. They advocate prompt débridement and end-to-end suture of divided nerve ends, with mobilization and transplantation of the nerve if necessary. The neuroma, once formed, should be dissected from the surrounding tissues and excised in slices until normal fasciculi are seen. In the case of amputation, ligation of the nerve is recommended in order to prevent oozing of blood from the nerve and. The nerve end should be allowed to retract into the soft tissues to avoid incorporation in the scar tissue. Nothing need be injected into the nerve.

D. NEELE ROCK, M.D.

In regard to the effect of splanchnicectomy on the amount of dilatation of the renal pelvis and calices, no change has been noticed in 5 cases but the dilatation increased in 1 case of bilateral tuberculous hydrocephrosis and decreased in 4 cases.

In 5 cases the author performed an extirpation of the splanchnic ganglion or a denervation of the renal plexus. After the operation the pains stopped but the morphologic changes remained stationary. The best results were obtained from splanchnicectomy combined with extirpation of the external horn of the semilunar ganglion and of the first ganglion of the lumbar sympathetic chain. In all such cases the relief of pain was accompanied by an objective improvement in the form of a diminution of organic lesions.

An infiltration of the splanchnic nerve is useful as a test if a transient improvement is obtained, an operation is justified. In 1 case of bilateral hydro-necrosis the author successfully employed splanchnicectomy on the more affected side and injection of an anesthetic on the other side.

There are three methods of approach to the splanchnic nerve: the posterior mediastinal approach, the infrapleural route and the lumbar subdiaphragmatic method, which the author prefers to the other two. Although the wound is deep and it is difficult to employ local anesthesia, pleural irritation is avoided and the approach offers the opportunity to examine the suprarenal glands and if desired to extirpate the semilunar ganglion. The

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Herrmann J B Adair F E. and Woodward H. O.: The Effect of Estrogenic Hormone on Advanced Carcinoma of the Female Breast
Arch. Surg. 1947 54 1

The favorable results obtained by a group of English investigators from the use of estrogenic hormones in some cases of advanced carcinoma in the female prompted the authors to try this therapeutic procedure. Seventeen patients were selected. Of these 13 had primary inoperable cancer for which no previous therapy had been administered a patients had recurrent lesions in the same breast several years after treatment of inoperable carcinoma by irradiation in 1 patient, a carcinomatous ulcer had developed in the mastectomy scar and in the remaining of the thoracic wall. A biopsy specimen, positive for cancer was obtained in every case.

These 17 patients were treated exclusively with a synthetic estrogenic hormone (ethinyl estradiol) administered orally. One milligram of this substance in the opinion of some investigators, is the equivalent of from 7 to 20 milligrams of diethylstilbestrol. In the present investigation, the dose of ethinyl estradiol varied from 0.15 to 0.7 milligrams daily. On the basis of the lower figure given previously this dosage would be equivalent to at least 1.0 to 5.0 milligrams of diethylstilbestrol daily.

The duration of the treatment with estrogenic hormones varied from 2 to 21 months.

To date, the cases of only one group of patients with advanced carcinoma of the breast, treated by 10 English investigators who pooled their cases (a total of 100) and presented them in a symposium. The authors findings do not differ essentially from those of the English investigators. An important point of agreement is that the favorable results have been predominant in women above the age of 60.

The results of the present investigation suggest a decidedly deleterious effect of estrogens on women in the younger age group. The effects were most striking in a 40 year old patient who was menstruating regularly. When first seen her general condition was good despite the mass in the right breast and axilla. Roentgenograms revealed no evidence of disease in the lungs, the lumbar portion of the spine or the pelvis. Soon after the institution of the estrogen therapy her condition deteriorated and death occurred about 1 month later. The rapid progress of the disease may have been the result of a specific action of the estrogen, or it may have been the result of vascular changes produced in the breast by the hormone. Illustrations showing the progress of the disease accompany the article.

Both estrogens and androgens apparently exert an inhibitory effect on carcinoma of the female breast. The pituitary gland may be the common denominator. Moore and Price have presented evidence that the pituitary may be influenced by the sex hormones. They found that gonadal hormones of either sex exert a depressing effect on the hypophysis of male rats resulting in a diminished amount of the sex stimulating factor available to the organism. Badger and his coworkers concluded from their researches that some synthetic estrogens exert an inhibition of growth on animal neoplasms. In their opinion the action might be in part local on the tumor cells and in part central on the pituitary.

In conclusion, the authors state that a favorable response was noted in 7 or 40 per cent of the patients—5 with superficial lesions of the soft parts and 2 with pulmonary metastases the response occurred predominantly in women over 60 years the skin of the breasts in elderly women may become pink and the mammae engorged the dosages employed induced uterine bleeding sometimes severe in over 50 per cent of the patients vaginal smears were studied in 6 patients all of whom showed a well developed estrus reaction there is suggestive evidence that in young women estrogenic hormones may accelerate the progress of the disease there were no changes in serum calcium, protein or alkaline phosphatase levels that could be ascribed to the administration of daily doses of an estrogen (ethinyl estradiol). A fall in the serum phosphorus level was observed in a large percentage of cases hyperglycemia was decidedly reduced in 1 patient solely by the use of estrogen.

JOHN J. MALONEY, M.D.

TRACHEA, LUNGS, AND PLEURA

Fisher G. E.: Primary Neoplasms of the Trachea.
South Surgeon 1947 13 78.

Abnormal growth of the cells composing the undifferentiated basal layer of pseudostratified epithelium has the potentiality of producing columnar squamous or glandular epithelium which may result in various forms of neoplasms. The type of tumors reported that could be determined histologically have been listed as fibromas papillomas, lipomas, chondromas adenomas lymphomas, intratracheal goiter angiomas cylindromas sarcomas carcinomas and endotheliomas. This great variation in the histologic structure of tracheal neoplasms obviously indicates that there will be a similar variation in the rapidity of growth in individual tumors.

The cardinal signs and symptoms are cough, dyspnea and hemoptysis. As the growth increases in size cyanosis may develop because of increasing obstruction of the tracheal lumen. Apnea and suffocation will eventually develop if the growth cannot be controlled.

The author reports 1 case of a female, aged 60, whose chief complaint was "asthma" from which she had suffered 8 years. She had hemoptysis and blood streaked sputum. The patient was bronchoscoped just above the bifurcation of the trachea a large growth was encountered which arose from the left posterolateral wall of the trachea and filled approximately 80 per cent of the tracheal lumen. It extended downward obstructing the left main bronchial orifice. A biopsy diagnosis of carcinoid was made on morphological similarities.

The patient was bronchoscoped with an 8 mm. instrument, and the tumor was partially removed with biting forceps and as thoroughly cauterized with electrocoagulation as deemed advisable at the time. Postoperatively there was considerable improvement and a definite partial re-expansion of the left lung.

Diagnosis is most easily made upon bronchoscopic examination of the growth biopsy and microscopic examination of the tissue removed. The most satisfactory means of treatment is fulguration of the growth by means of electrocoagulation through the bronchoscope, accompanied by deep roentgen ray therapy

LEE PULLER M.D

Oversholt, R. H., Langer L., Szypulski, J. T., and Wilson, N. J.: Pulmonary Resection in the Treatment of Tuberculosis. *J. Thorac. Surg.* 1946, 15 384.

The present day operative procedure of pulmonary resection, the risk as to postoperative complications, and the mortality are discussed. The status of a consecutive series of 193 patients on whom 300 resections were performed, is reported.

The use of the lateral position for pulmonary resection has 2 disadvantages (1) the diseased side is directly over the sound side, favoring gravity drainage of secretions from the bad to the good lung, and (2) excursions of the thoracic cage and diaphragm on the sound side are impaired by the weight of the body. In an attempt to reverse the relative positions of the two lungs during operation, the patient is suspended face down and his chest turned so that the sound lung is uppermost. This new position is advantageous from several points of view (1) operative contralateral spread of the disease has been reduced from 19 to 10 per cent (2) the possible range of respiratory excursions is greater and patients adjust themselves better to open pneumothorax, (3) the amplitude of the mediastinal swing, or displacement, is greatly reduced (4) the use of intrabronchial positive pressure can be eliminated in most cases (5) exposure of the posterior aspect of the hilum is facilitated (6) the weight of the lung allows it to fall forward, which eliminates the need for holding it up, or the use of traction during dissection and (7) cardiac irregularities and standstill have been practically eliminated as complications.

A method of paravertebral block anesthesia and intratracheal intubation after topical application has been developed, with these advantages (1) a

better control of intrabronchial secretions can be obtained retained secretions in the abnormal lung are not released by bronchial relaxation aspirations do not disturb the plane of anesthesia, or result in periods of anoxia the cough reflex is present throughout the operation (2) the anesthetic agent is less toxic; and (3) the immediate postoperative condition of the patient is better. With the use of paravertebral block and local infiltration with novocain, the incidence of contralateral spread has been reduced from 19 to 10 per cent.

Pulmonary resection is not a competitive, but a supplementary form of treatment to the collapse therapy procedures. The series of patients presented cannot be compared with any thoracoplasty series, since complicated forms of tuberculosis were present, in which collapse therapy had failed, or which were unsuited for thoracoplasty. Upper lobectomy should not be performed as an elective procedure when there is a reasonable chance to control the lesion by thoracoplasty because ipsilateral exacerbation of the remaining foci frequently occurs.

Technical maneuvers considered to be particularly important are (1) avoidance of lung clamps (2) avoidance of contamination from the lung or cut bronchus (3) early preliminary bronchial ligation, (4) pleural flap re-enforcement of the bronchial stump and (5) routine bronchoscopy after resection to ascertain the condition of the bronchial stump.

A final appraisal of the value of resection in the treatment of tuberculosis cannot as yet be made. Larger series of patients must be studied for longer periods of time.

SAMUEL KATZ M.D.

Decker H. R.: The Treatment of Thoracic Actinomycosis by Penicillin and Sulfonamide Drugs. *J. Thorac. Surg.* 1946, 5 430.

While actinomycosis (streptothricosis and nocardiosis) is the most common of systemic mycoses, it remains a comparatively rare disease. There has been some confusion in the classification of the Actinomycetes. In the war 3 types have been recognized as pathogenic to man (1) the Actinomyces bovis, an anaerobic form which is gram positive and nonacid fast and (2) the Nocardia asteroides, an aerobic acid fast group, which includes the Actinomyces gypseoides. Nocardia madurae is an aerobic nonacid fast group. Both types produce mycelia, which form tangled masses of filaments recognized as "sulfur granules."

Characteristically these fungi produce a chronic granulomatous type of inflammation in which suppuration, abscesses, and sinuses develop and dense scar tissue is produced in excess. The inflammation burrows through tissue with no respect for normal fascial planes and anatomic barriers. The dense fibrous tissue diminishes vascularity and renders the lesions less permeable to the action of drugs. Superimposed on the actinomycotic process, there is often secondary infection due to pyogenic bacteria.

Infection of the lung may be air borne or from fungi aspirated from the mouth, teeth, and tonsils.

Three types of thoracic disease are differentiated but are really all part of one process (1) bronchitic, in which the invasion usually starts in the bronchi, but is rarely confined to the bronchial tree (2) pneumonia, a bronchopneumonia in which the lung parenchyma is replaced by nodular or diffuse caseating infiltration which breaks down into abscesses (The usual location is in the lower or central parts of the lungs) and (3) pleuritic found in cases in which the invasion is most extensive in the pleura whence the disease spreads to involve the chest wall whence the form anywhere but commonly near the breast and axilla where sinuses develop. The ribs are invaded in 25 per cent of the cases and the vertebrae in 10 per cent the sternum is invaded only occasionally.

Cough is the first symptom at first it is dry but later there is mucoid sputum which becomes purulent and blood streaked. Hemorrhage is rare. Intermittent fever dyspnea malaise night sweats and loss of weight follow. Pain appears when the pleura is involved. Secondary anemia and high leucocytosis are common. Physical signs depend on the character of the pulmonary and pleural involvement. The picture is suggestive of tuberculosis. Early infiltration then areas of consolidation appear with abscess formation thickening of the pleura or pleural effusion. The picture is not distinctive but marked pleural thickening erosion of the ribs and fracture of the chest wall and narrowing of the pulmonary fields are suggestive.

The early diagnosis of thoracic actinomycosis is difficult to make. It is established definitely by finding characteristic mycelia or sulfur granules in pus or fixed tissue sections. The differential diagnosis must be made from tuberculosis pyogenic abscess bronchiectasis and empyema due to pyogenic bacteria.

In the treatment surgery is essential. Abscesses should be drained sinuses of the chest wall excised diseased rib removed and involved portions of the long ablated. Sulfonamides may exercise a favorable influence on the disease because of their effect on the secondary pyogenic infection. The early favorable response to sulfonamides is very often not maintained.

Penicillin is the best therapeutic agent for actinomycosis of the chest as well as for actinomycosis elsewhere in the body. If administered early it causes arrest of the disease and recovery in any case. In most cases penicillin produces a favorable outcome even in long standing cases especially if it is used with sulfonamides to clear the secondary process of infection.

Large doses of penicillin 1 ft. in 100 000 to 200 000 units a day for about 2 weeks should be given in some strains of actinomyces are fairly in susceptible to a plate test or truth culture reaction may be the proper guide for dosage. After several weeks a further course of penicillin treatment should be given as the fungus may remain latent and the penicillin repeated courses of penicillin treatment

should be given for a year and at any time when symptoms reappear. Intramuscular administration is preferable but this may be combined with intrapleural or intrapulmonary injection.

SAMUEL KAHN, M.D.

Gladnikoff H.: Genesis of Bronchiectasis, an Unappreciated Bronchodilating Force. *Archs med* second 1946 126 411

There are two types of bronchiectasis, congenital and acquired. Congenital bronchiectasis is a rare condition, two forms of which have been described (a) fetal bronchiectasis and (b) atelectatic bronchiectasis in which the bronchi shortly after birth become gradually widened as a result of the developmental effect of collapse of the pulmonary parenchyma. It is however extremely difficult to differentiate between the strictly congenital and the metapneumonic atelectatic, or idiopathic. The author discusses the literature on bronchiectasis going back as far as Laennec's original description in 1819 as well as the causes and treatment of the condition.

It is believed that pressure of secretion behind a bronchial wall may be possible cause of injury to the occasional cases of bronchiectasis.

The inspiratory movements of the thoracic wall and the diaphragm are a bronchodilating force of considerable magnitude when their impulses are transmitted to air-conveying bronchi through nonair-conveying lung tissue. The author believes it is possible that this force exceeds the tolerance of the bronchial walls under certain conditions. Clinical roentgenological and morbid anatomical observations in pneumonia and atelectasis as well as during the genesis of bronchiectasis have shown this bronchodilating force to be the usual and possibly the only cause for the genesis of bronchiectasis.

Diagnosis while the bronchial dilatation is reversible is essential for conservative treatment. For this reason bronchography should be carried out in all cases of pneumonia and atelectasis which cannot be checked quickly or in cases of relapse particularly in children.

Apart from combating infection, the treatment of reversible bronchial dilatation should be directed towards the elimination of abnormal bronchodilating forces. With this object in view the cause of the genesis of the bronchial dilatation justifies steps for the rapid re-aeration of the consolidated lung tissue. If this proves impossible the artificial pneumothorax should be accomplished but the lung should not be collapsed. If pneumothorax is impossible it may be necessary to perform a unilateral phrenicotomy.

PAUL STREBEL, M.D.

Kay E. D. Meade R. H., Jr. and Hughes F. A. Jr.: The Surgical Treatment of Bronchiectasis. *Am. J. Surg.* 1947 1: 1

The clinical course of bronchiectasis is characterized by chronic relapsing varying degrees of delirium

and, usually recurring attacks of pneumonia. There may be remissions with relative freedom from symptoms. The degree of disability is largely dependent on the degree of sepsis, which is dependent on the adequacy of bronchial drainage.

The destructive changes in bronchiectasis are permanent. In the development of the disease, the ciliated columnar epithelium is frequently ulcerated and replaced by nonciliated cuboidal or squamous epithelium, and the normal elastic tissue and smooth muscle fibers are partially or completely replaced by granulation or scar tissue. Because of the loss of the normal cleansing action of the bronchial tree, due to the loss of the ciliary action of the mucous membrane and the peristaltic action of the bronchial wall stasis of the exudate and resulting infection occur.

The prognosis of patients with untreated or medically treated bronchiectasis is poor. The mortality rate is said to be higher when the bronchiectasis is cystic (55%) or saccular (37%) than when cylindrical (13%). The morbidity is also considerable. Conservative therapy to improve bronchial drainage combat infection, and improve the general condition of the patient is of value. Postural and bronchoscopic drainage, breathing and coughing exercises, eradication of other foci of infection, a high caloric diet, vitamin therapy and medication to thin the viscid bronchial exudate are all valuable adjuncts in the treatment of bronchiectasis. Penicillin is of value in the treatment of the recurrent pneumonic episodes and also decreases the sepsis and intoxication during the interval stages. But symptomatic treatment is only temporizing with the disease. Death from bronchiectasis usually results from pneumonia, septicemia, pericarditis, failure of the right side of the heart, hemorrhage, or empyema. These hazards are present as long as the disease exists.

Permanent cure can be obtained only by pulmonary resection. The operative mortality and morbidity are very small at the present time. Only 1 death occurred among 220 consecutive lobectomies. One hundred and eighty-four lobectomies were done for bronchiectasis, 20 for pulmonary cysts, 11 for chronic pulmonary suppuration, 3 for bronchial adenomas and 3 for basilar tuberculosis. The bronchiectasis in patients not operated on was either too minimal or too extensive.

The decision as to the advisability of operation depends on the amount of disability, the extent of the destructive changes and the evidence of chronic intoxication. Patients who present no significant clinical evidence of the disease and those with minimal bronchiectasis can be cared for conservatively. Those in whom all 3 lobes are involved are beyond surgical treatment. In the other cases, lobectomy is recommended if there are no contraindications to operation. The field of operability now includes

with extensive bronchiectasis on one side and minimal disease on the other or with extensive bilateral bronchiectasis as long as the right upper lobe and upper aspect of the left upper lobe are normal and the cardiorespiratory reserve is adequate.

Adequate bronchograms should be made to ascertain the degree and distribution of the bronchiectasis present. Careful bronchoscopy should be done to determine from which lobes most of the exudate is escaping and the presence of unduly active inflammation of the bronchial mucosa, to improve drainage, and to eliminate the possibility of the presence of foreign bodies or tumors. Bronchospirometric studies to determine which is the worse side in bilateral cases, the pulmonary reserve of the uninvolved lung in dyspneic patients, and the extent of functional tissue in borderline cases, have been found to be of value.

The operation should be postponed until the patient is in as good condition as possible. From 4 to 6 weeks should elapse after bronchography to allow elimination of the iodized oil. During this time the patient is placed on a high caloric, high vitamin diet. Postural drainage should be used. A course of penicillin given through the trachea is of value in patients with copious sputum. Penicillin is given intramuscularly on the evening before operation.

All the operations have been done by the individual ligation technique. The posterolateral approach with resection of the seventh rib or the lateral approach with resection of the sixth rib gives good exposure. Elevation of the head of the operating table in combination with early operative occlusion of the bronchus keeps the exudate in the bronchiectatic abscesses and does not allow it to drain into the main bronchi and cause obstruction and perhaps, be aspirated into the opposite lung. Secure closure of the bronchial stump largely determines the postoperative course. The bronchus should be amputated high, to prevent puddling of secretions at the site of amputation later. Silk technique is used throughout. All pleuritic adhesions between the upper lobe and chest wall are severed, since they prevent the upper lobe from readjusting itself to the larger space allotted to it. Blood transfusions are begun at the outset of the operation and continued throughout its course. Usually from 500 to 1,500 c. c. of blood suffice.

Postoperatively adequate oxygenation is provided by tent or intranasal oxygen for about 24 hours. Frequent intratracheal aspiration, insistence on coughing, deep breathing exercises and frequent change in position help to maintain an open tracheobronchial airway which is essential to early expansion of the remaining lobe and obliteration of the pleural space. Penicillin is given intramuscularly for 7 days. The patient is routinely gotten up by the third postoperative day.

In only 1 patient did significant shock from blood loss develop. Bronchopleural fistulas with resulting empyemas occurred in 20 cases. Atelectasis occurred in 3 cases because of intrabronchial exudate and occlusion.

Postoperative bronchospirometric studies on 26 patients demonstrated that the function of the remaining pulmonary tissue on the operated side is

influenced greatly by the postoperative pleural complications. In no instance was the pulmonary function significantly impaired following an uneventful lobectomy. Apparently the bronchiectatic lobe contributes very little to the oxygenation of blood circulating in its pulmonary tissue as the blood returns to the heart unoxygenated and with a high carbon dioxide content. This is largely responsible for the cyanosis and dyspnea seen in these patients. On removal of the bronchiectatic tissue the blood can then be circulated only through alveoli that allow proper oxygenation and diffusion of gases.

SAUEL KAHN, M.D.

Mattel C., Tristani, M. and Barbe, A.: Roentgenographic Aspect of the Zonal Catheterization of the Lung during the Endobronchial Instillations of Penicillin in the Treatment of Pulmonary Abscesses (Aspect radiologique des cathétérismes zonales du poumon au cours de la pénicilliothérapie endobronchique des abcès pulmonaires) *Press. méd.*, 1946 54 638.

The zones of aeration in the pulmonary parenchyma with bronchial and vascular autonomy as described by Lucien Grandjean Weber and Beau De Pierret, Coulouma, Breton and Devos have been found to be accurate and of great practical value by the authors for localizing pulmonary lesions and catheterizing the bronchi.

A brief anatomical review of the topography of these zones of aeration is given, and the schema of Lucien and Beau is reproduced (Fig. 1).

The authors have performed 1,100 bronchial catheterizations without the use of the bronchoscope under local anesthesia, using pontocaine. A 1 per cent solution was used in the pharynx and larynx, and a 0.5 per cent solution in the trachea and bronchi. Treatment was given for 63 pulmonary abscesses and various bronchial suppurative processes. They advocate the use of a curved rubber sound with an extremely opaque tip. The 63 abscesses were localized in the following zones: 40 per cent in the upper dorsal, 13 per cent in the apical, 15 per cent in the anterior zone of the middle lobe, 13 per cent in the upper area of the lower lobe and 19 per cent in the remaining zones.

All those catheterizations were made in order to deposit the penicillin as close as possible to the abscess which had been accurately localized. The authors are convinced that the solution of penicillin as well as the lipidol often reaches the foci of suppuration as illustrated by roentgenographic study.

The authors reported on 50 cases of pulmonary abscess with a complete study and follow-up, 49 of the abscesses had been active for more than 2 months. It is believed that 20 (40%) clinical and roentgenographic cures were maintained from 6 to 12 months. In 16 (32%) of the cases clinical improvement was obtained but there was persistence of a few roentgenographic findings. In 5 cases (10%) there was improvement characterized by disappearance of the foul odor and almost complete suppression of expectoration and marked improvement of

Fig. 1 (Mattel *et al.*) Upper lobe 1 apical area, 2 dorsal, 3 external 4, ventral. Middle or lingual lobe in the left lung; 5 external 6 posteroexternal 7 anterointernal Lower lobe 8, ventrodorsal, 9, laterobasal 10, dorsobasal 11 infracardiac 12, mid-dorsal. The numbering of the bronchi correspond to those of the zones which they ventilate. (Thirteen other patients under treatment had similar localizations.)

the general condition of the patient but persistence of the roentgenographic findings. Finally, the authors state that there were 9 (18%) failures, of which 6 occurred in cases presenting neoplasms. In these cases only the amount of suppuration was diminished. Three cases presented true abscesses and made absolutely no response to treatment. Two of the abscesses were in polycystic cavities and 1 abscess was an atypical one with no collapsible cavity.

These results, which seem to stand the test of time so far, prove the value of this simple method of endobronchial instillation of penicillin in the treatment of pulmonary abscesses.

GERARD GAUMON, M.D.

Soubrié A., Morera J. and Labourt F. E.: The Incidence of Pleuropulmonary Perforation following Intrapleural Pneumolysis, as Determined by Analyses of the Intrapleural Gases (Frecuencia de la perforación pleuro-pulmonar en la neumonolisis intrapleural. Estudio de los gases pleurales) *An. Cated. pat. clin. labor.* 1945 7 330.

The composition of pneumothorax gases was determined before and after intrapleural pneumolysis in 50 patients. Based on these findings, evidence of bronchopleural communication was found in 5 cases after the division of substantial adhesions and in 1 case it was recorded after the sectioning of filmy adhesions only. The authors thus consider the incidence of such fistulas as a result of the operation to be 10 per cent.

In 3 cases evidence of a fistula was encountered before operation.

The results of the analyses in these 50 cases are given.

HIRSH T. LANGSTON M.D.

Kantorik, R.: Superior Pulmonary Sulcus Tumors (Nádory plicních hrotů) *Lék Hstý* 1946 1: 354.

Malignant tumors of the pulmonary apices demand for their recognition not only a close roentgenographic study including tomography and perhaps kymography but also close clinical observation of the characteristics and development of the morbid process. The most typical malignant growth in this region is that denominated by Pancoast, the superior pulmonary sulcus tumor. This particular growth is characterized, as a rule, by a very striking combination of symptoms, including a peculiar form of neuralgic involvement of the brachial plexus, with pains in the arm and shoulder, insensibility of the elbow region, and sensations of burning and formication in the regions of the hand and fingers of the involved side. When this tumor is present the sympathetic is also very frequently involved, which results in a Horner's syndrome. The third characteristic of Pancoast's tumor is the roentgenological evidence of the eroding effects on the ribs, particularly the posterior section of the third rib. The roentgen findings, of course, are similar for all the tumors in this region. However the sarcoma is more sensitive to irradiation therapy and the endothelioma, arising from the pleura, grows more slowly. However the carcinoma is sufficiently sensitive to be reduced in size by roentgen therapy which does not, however hinder its strong tendencies toward metastasis.

Differential diagnosis is a difficult problem in tumors of this region. Of chief concern, of course, is the evidence of healed tuberculosis with its cicatricial retraction and infiltration. However a tumor should be easily distinguishable not only through its constant growth in size, but also through its deeper more homogenous and smooth bordered shadow. Metastases in this region are usually recognizable as such not only through their usual multiplicity but also by evidence of the parent tumor elsewhere. Atelectasis is an important thing to look for in the surrounding lung tissues since it is frequently absent in the presence of shadows of other origin than tumor (lymphogranulomatosis, actinomycosis, Hodgkin's disease).

Nevertheless, the diagnosis of the condition present in this region will often prove to be a tremendous problem, and in the final paragraph the author suggests that the diagnosing physician depends on a certain amount of intuitive feeling but always, of course, tries to make the diagnosis on an objective basis.

JOHN W. BRUNNER M.D.

HEART AND PERICARDIUM

Mahre, E. D.: Coarctation of the Aorta. *N. England J. M.*, 1947 36.

Advances made by surgeons in handling the great blood vessels have stimulated new interest in coarctation

of the aorta. The author's case presentation includes a discussion which re-emphasizes much of what Sir Thomas Lewis wrote about this subject.

Coarctation of the aorta is generally classified into two anatomic groups, both of which are located, for the most part, in the distal portions of the arch: (1) the first form, known as the infantile type, is characterized by a generalized narrowing of the arch in its distal portion, extending from the origin of the left subclavian artery to the region of the ductus arteriosus (Clinically this is a rare form and is so frequently accompanied by other major cardiac anomalies that death occurs in infancy) and (2) the adult type is characterized by an abrupt narrowing, sometimes to the point of obliteration, of the aorta in the proximity of the insertion of the ligamentum arteriosum (This is not a rarity various observers having reported an incidence of 1 in 150 cases at autopsy). The more favorable life expectancy in the second group results from an adequately compensating collateral circulation, as well as from the fact that the associated developmental anomalies, if any, are less serious than those found in the infantile type. In the main, these anomalies fall into two groups: (1) those of the heart and great vessels, including bicuspid aortic valves, anomalous origin of the arteries of the aortic arch, persistent left superior vena cava, aortic septal defects, and subaortic stenosis and (2) anomalies of the body at large, such as hypospadias, absence of a kidney, vertical position of the stomach, horseshoe kidney, diaphragmatic hernia, subluxation of the joint, slight mongolism, ichthyosis, pigeon breast, and congenital cerebral vessel aneurysm.

Embryologists give the following explanations of the development of coarctation of the aorta of the adult type:

1. (Brunner) The tissue of the ductus arteriosus, at its junction with the aorta, which shortly after birth becomes completely stenosed, anomalously incorporates the contiguous portion of the aorta in this obliterating action. The primitive fourth arch (aorta) falls prey to the obliterating action of the primitive sixth arch (ductus).

2. Others point out that the ligamentum arteriosum exerts a ropelike tugging on the aorta at the junction of the two, which causes a kinking of the aorta that results in stenosis.

3. (Reynaud and Rokitsansky) Embryonic maldevelopment of the descending limbs of the primitive left aorta causes the coarctation in those cases in which stenosis occurs proximal to the origin of the left subclavian artery or in the abdominal aorta.

The important symptoms of the adult type, beginning after years of apparent good health, consist mainly of breathlessness and palpitation after exertion, fatigability, slight cough, sometimes giddiness with hot flushing of the face, headaches, and thoracic pain. (The author's patient was referred by a neuro-psychiatrist to whom he had been sent because of nervousness.) The physical signs include

1. Foremost, the reversed relation of the brachial and popliteal arterial blood pressures.

2. The femoral pulsation is weaker with a definite lag in its summation, compared to that of the radial pulse; the lag is 0.145 of a second according to accurate measurement by Sir Thomas Lewis.

3. Visual, palpable, or auditory evidence of increased pulsations of various arterial branches of the aorta.

4. Sulcation along the inferior margin of the posterior portions of the ribs.

5. Absence of the aortic knob and extension toward the neck of the silhouette of the supracardiac vessels.

The author makes the well taken point that too often in cases of hypertension no effort is made to determine the blood pressure in the lower extremities, so that without any doubt cases of coarctation of the aorta are frequently missed.

EUGENE J. AUDI, M.D.

ESOPHAGUS AND MEDIASTINUM

Udde G I: Chemical Burns of the Esophagus. *Ann Otol Rhinol.*, 1946 55 795

The clinical records of all patients treated for chemical burns of the esophagus at the University of Oregon Medical School Hospitals during a 15 year period were reviewed. An analysis of these findings is presented.

In the present series, there were no deaths as a result of personal instrumentation. The esophageal findings at autopsy in one case of burns due to a silver salt, lactic acid and lyo are given. The patient in this case died of brain abscesses of both temporal lobes, which is interesting in view of the fact that deaths from brain abscesses under similar conditions have been reported by other authors. The course of action taken at this hospital in the treatment of acute esophageal burns together with arguments pro and con, is discussed.

The following procedure is carried out in all cases of esophageal burns: (1) immediate neutralization of the poison (2) immediate swallowing of a size D twisted (not braided) silk thread on completion of procedure 1, (3) treatment to avoid dehydration and starvation, (4) consultation with an otolaryngologist within 24 hours (5) examination with barium under fluoroscopy and with flat plates as soon as the initial fever subsides usually in 7 to 10 days (6) esophagostomy after determination of the site and degree of obstruction by procedure 5 (7) following the esophagus bouginage up to 45 French in an adult with mercury bougies of the Salzer or Bokay types, carried out once or twice weekly or less often depending upon the stricture's reaction to bouginage and the patient's ability to swallow. Bouginage is performed over a period of 6 months to a year, depending upon the results (8) if frequent bouginage is unsuccessful that is, if the child is in danger of becoming malnourished with a retardation in normal development, a gastrostomy is performed, the esophagus is dilated at rest, and the stricture is dilated in the retrograde manner advocated by Tucker.

JOHN J. MALONEY, M.D.

Ladd W E and Swenson O: Esophageal Atresia and Tracheoesophageal Fistula. *Ann Surg* 1947 125 33

Esophageal atresia and tracheoesophageal fistula received comparatively little recognition and aroused little interest among clinicians until the last decade. The anomaly is quite common occurring about as frequently as harelip and cleft palate.

There is a wide variation in the pathologic findings. No 2 cases are exactly alike. Ladd describes 5 types. In Type I the upper portion of the esophagus ends in a blind pouch in the region of the body of the first or second dorsal vertebra, and the lower segment of the esophagus begins again in a blind pouch at the level of the fourth or fifth dorsal vertebra. In Type II the upper segment of the esophagus ends in a fistulous tract entering the trachea just above its bifurcation, whereas the lower segment is much the same as in Type I. In Type III, the upper segment ends blindly as in Type I whereas the lower segment is connected to the trachea by a fistulous tract just above the bifurcation. This type and Type IV are by far the most common in the reports of the literature as well as in the authors' experience. Type IV is similar to Type III except that the fistulous tract of the lower segment enters the trachea at its carina instead of just above its bifurcation. In Type V both the upper and lower segments communicate with the trachea.

If a newborn infant becomes cyanotic and shows an excess of saliva or frothy mucus in the mouth the diagnosis of esophageal atresia should be considered. If subsequently the infant vomits all fluid offered almost immediately after it is given the diagnosis should be strongly suspected and steps taken to confirm or disprove the suspicion. First, a No. 8-F or 10-F soft rubber catheter should be introduced into the esophagus, preferably under the fluoroscope, and if this meets an obstruction 10 or 12 cm. from the lips the diagnosis is confirmed. The diagnosis should now differentiate between the types of the malformation, which is done with the help of the roentgen rays.

The preoperative preparation of these patients is important. They should be placed in an oxygen tent for the administration of oxygen in high concentration. Then a small soft rubber catheter is introduced into the pharynx and attached to constant suction. By this means and by keeping the infant in a slight Trendelenburg position the air passage can be kept fairly clear and respiration made much easier. Transfusion and parenteral fluids should be given as indicated.

All attempts to remedy esophageal atresia with tracheoesophageal fistula without direct ligation of the fistula have failed. The retropleural operation through the right side of the back has given the best results, and cyclopropane has been the anesthetic of choice.

After dissection down to the segments of the esophagus, judgment and experience are of value in

Fig. 2. (Ladd, Swenson) Diagram showing the arrangement of the trachea and esophagus in 5 types of esophageal atresia and tracheoesophageal fistula. The letters refer to the following structures: A, trachea; B, bifurcation of trachea; C, upper segment of esophagus, and D lower segment of esophagus. (New England Journal of Medicine.)

determining whether a primary anastomosis should be attempted, or the simpler operation of tying and cutting the tracheoesophageal fistula should be done. The decision depends on the condition of the patient and the distance between the two ends of the esophagus. If the space between the two segments is much over 5 cm., the chance of performing an anastomosis without tension is not good.

When the conditions indicate, an end-to-end anastomosis is done, the upper blind end being freed well up above the first rib, so that it can be brought to the lower end without tension. The lower segment is isolated and cut away from the trachea almost in the tracheal wall, in order to give it maximum length. As the esophagus is separated from the trachea, the opening into the trachea is closed by a running suture of fine silk, and this row of sutures is in turn, covered by a second layer of running sutures of the same material. The final step is the suturing together of the two ends.

In patients in whom the ends are too widely separated to warrant a primary anastomosis, a multiple stage procedure is adopted. At the first operation the site of the atresia is approached as described for primary anastomosis. The lower segment of the esophagus is cut away from the trachea at the site of the fistula, both ends are tied, and an over-and-over stitch is placed to insure against leakage. This having been done, the chest wall is closed.

During the next few days the patient is kept in slight Trendelenburg position and constant suction is applied to the upper segment of the esophagus to prevent aspiration of saliva and mucus. In this interim the baby's fluid balance is maintained by the intravenous administration of blood or plasma, and saline or glucose solution. At the end of 5 or 7 days, under local or cyclopropane anesthesia, a gastrostomy is performed through a high left rectus incision. This enables the infant to be fed and obviates the necessity of continuing parenteral fluids.

The third stage of the operation is performed 7 or 8 days after the gastrostomy and consists of bringing the upper segment of the esophagus out in the neck.

After these procedures have been completed, an indefinite period elapses before an anterior thoracic esophagus is constructed. The stomach and esophagus can be connected by an epithelial lined tube made over the left chest wall and covered by a tubed graft taken from the right axilla. In other cases a segment of jejunum is attached to the lower end of the skin tube. An appropriate loop is freed, the jejunum divided and the proximal end closed. A side to side anastomosis is made between the closed jejunum and a loop farther distalward. The skin of the chest is tunneled under from the cephalic end of the incision through which the jejunal loop is secured to a point under the opening of the skin tube. The proximal end of the jejunal loop is drawn through this subcutaneous tunnel and sutured to the lower end of the skin tube. Provided there is no evidence of inflammation at the site of the dermo-jejunal anastomosis, the patient is given water by mouth on about the tenth postoperative day. These patients can swallow liquids and solids easily and only occasionally is it necessary to promote the emptying of the skin tube by manual pressure.

The authors appreciate that the mortality from esophageal atresia should be further reduced, but there undoubtedly will continue to be an appreciable mortality because of associated anomalies incompatible with life. Among the 76 cases reported in the article, there were 45 deaths, a mortality of 60 per cent.

STEPHEN A. ZIEGLER, M.D.

MISCELLANEOUS

Drash, E. C.: Intrathoracic Metallic Foreign Bodies. A Review of the Literature. *South. Surgeon*, 1947 13: 1.

During World War II, 8 out of 10 wounds were due to bullets and 8 were due to high explosive shells. About 10 per cent or less of retained foreign bodies are bullets the remainder are high explosive shell fragments. The mortality and morbidity of shell fragment wounds is higher because of their greater frequency the irregular fragments do more damage, and the wounds show a greater percentage of infections

because the shell fragments tend to carry extraneous material into the tissue.

In field and evacuation hospitals in Italy the treatment of chest injuries was primarily directed at the conservation of life by restoring normal cardiorespiratory physiology treating shock by blood replacement, and preventing infection.

In general, the majority of patients with thoracic wounds seen in forward hospitals, recovered on a system of blood replacement débridement and closure of chest wall wounds, aspiration of blood and air from the pleural space, insertion of an intercostal catheter for tension pneumothorax, and novocain in tercostal block for fractured ribs.

Operations other than simple débridement were done in forward hospitals only when there was evidence of gross continued bleeding uncontrolled bronchopleural fistulas, or evidence of transdiaphragmatic or esophageal injury.

In the Mediterranean Theater foreign bodies of over 1 cm. in greatest diameter in the pleura or lung, were to be removed in the thoracic surgical center in the base hospital. Operations were indicated for prevention of infection or removal of clotted blood from the pleural space. Failure of the lung to re-expand progressively and quickly within 4 weeks of adequate drainage was accepted as an indication for thoracotomy and decortication.

Foreign bodies causing symptoms should be removed as soon as expedient. Asymptomatic foreign bodies over 1.5 cm., were removed in from 4 days up to 3 weeks of injury. When present as long as from 3 to 4 weeks fibrosis about the foreign bodies made thoracotomy more difficult.

The validity of removing asymptomatic shell fragments as a prophylactic procedure can only be decided years later when operative morbidity rates are compared with the percentage of complications which develop in patients with retained shell fragments. Harkins reported that only 8 per cent of patients with chest wounds had foreign bodies which required removal. They were removed to prevent hemorrhage and suppuration. Other factors considered were size and irregularity proximity to major vessels and bronchi, dependent position in the parenchyma, and the surrounding reaction as determined clinically and by means of x-ray.

D Abreu reports a series of 260 cases of penetrating wounds of the thorax with 84 retained foreign bodies, 16 lung abscesses, 77 empyemas and 15 deaths.

Parker and Burford reported 75 serious complications among 291 cases of intrathoracic foreign bodies. These were empyema late or recurrent bronchopleural fistula, lung abscess, delayed or recurrent hemoptysis, secondary intrapleural hemorrhage from the lung, and mediastinal abscess. Ten per cent of their cases operated upon had complications.

Tudor Edwards condemns the removal of intrathoracic foreign bodies in forward hospitals since wounds heal well in the presence of uninfected foreign bodies. He points out complications may occur as late as 20 years after wounding. He removes large

foreign bodies when sepsis is not present in the fifth to sixth week. He thinks all irregular foreign bodies should be removed from the lung in order to prevent secondary lung changes.

Paine in a North African general hospital reported 66 patients with retained thoracic foreign bodies none of which were operated upon. None had complications and none had symptoms referable to the foreign bodies. Twenty five of his patients returned to duty.

Blades at Walter Reed thinks each case should be individualized and considers whether foreign bodies produce signs or symptoms, size and position of the fragment and the psychosomatic effect on the patient. He reports 30 cases of which 16 had removal with no deaths.

Garland in reporting his experience in a naval hospital had 130 cases of intrathoracic foreign bodies only 20 of which were causing symptoms. Removal was undertaken in 10 cases without a death.

The experience of thoracic surgeons in the chest centers of the United States is different than that of the overseas surgeons. Without the urgent need to return men to duty their attitude and approach is more conservative than that of the chest surgeon stationed in the forward zones.

Foreign body localizers were not very satisfactory and were little used. A bronchogram is often of value in designating the segment of the lung involved.

There is apparent uniform agreement that foreign bodies in and about the heart and pericardium should be removed if operation is feasible. This generally applies to mediastinal foreign bodies also because of the danger of erosion of important structures. In trapulmonary foreign bodies if small and multiple should not be removed according to the evidence presented. The lung tolerates rather well sterile metallic foreign bodies but not those associated with infection nor those consisting of cement bone clothing, or other organic material.

The late symptoms of foreign bodies consist of (1) migration symptoms (2) erosion of vessels or bronchi (3) recurrent infection (4) pleural irritation (5) nerve pressure, and (6) changes in adjacent structures due to the injury or presence of the foreign body.

Silent foreign bodies less than 2 cm. in diameter probably should not be removed. Larger foreign bodies should be removed to prevent late complications. Veterans who present themselves for consideration of removal of intrathoracic foreign bodies should be carefully studied to see if the symptoms are actually due to the foreign body or are psychosomatic in nature. The removal of foreign bodies in a small number of cases may be justified on the latter basis after psychiatric consultation.

ROBERT R. BRIDLOW, M.D.

Colombo C.: Contusions of the Thorax (Contusioni del torace). *Minerva med.*, Tor. 1946 37 378.

The author reviews the types of thoracic injuries caused by contusion and makes brief suggestions concerning therapy. Under lesions of the thoracic cage are included superficial contusions of the chest

wall contusions of the breast (particularly during lactation) sternalocostals, fractures of the ribs, clavicle, and sternum, and luxation of the clavicle. Attention is directed to the syndrome of thoracic shock resulting from trauma of more or less violence but of brief duration and believed to be due to a disturbance of the autonomic system which results in splanchnic vasodilatation. In contradistinction is the syndrome of thoracic compression or traumatic asphyxia due to long continued reduction of the chest capacity which probably exerts pressure on the superior vena cava.

Under intrathoracic syndromes resulting from contusion injuries are listed lacerations of the parietal pleura, subcutaneous emphysema, pneumothorax, mediastinal emphysema, hemothorax and empyema. Space is devoted to the diagnosis and treatment of pneumothorax under pressure and the strain of the right side of the heart which may occur in that condition. Brief mention is made of lesions involving the pericardium, the heart, and the great vessels in the mediastinum, and in conclusion, of lacerations of the thoracic duct, esophagus, and thymus.

FORREST B. FAIRBANKS, M.D.

Candolin, Y.: On Diaphragmatic Hernia. *Acta chir scand* 1947 95 6

Diaphragmatic hernia may not be a very common affection but the author believes that it is by no means as rare as it is often held to be, because of the fact that an erroneous diagnosis is frequently made. This tendency is facilitated on the one hand by the fact that the hernia is situated deep in the center of the body, resulting in indefinite and obscure symptoms, and on the other hand by the fact that the etiology varies. With the development of diagnostic facilities there follows a rise in the number of cases met with thus 30 cases were diagnosed as diaphragmatic hernia at the Mayo Clinic during the 25 year

period from 1900 to 1925 and 197 cases have been observed during the ten year period from 1925 to 1935. Diaphragmatic hernias may be grouped into several different classes according to their origin, namely traumatic, congenital and so called acquired hernias. They are classified further as genuine with a hernial sac, and as false without it.

The author stresses the fact that the only means of curing diaphragmatic hernia is by operation. He reviews 8 personal cases and points out the most common locations of hernia through the diaphragm. He summarizes his cases as follows:

Eight cases of diaphragmatic hernia have been observed at the Central Hospital of Abo since 1934. In 4 of these the hernia was the result of a perforating trauma and in 1 case the result of blunt trauma. In 3 cases the condition was congenital and in 1 case the patient had a hiatus hernia. In 4 cases the hernia was incarcerated and in 1 of these the incarceration arose in connection with a six months' pregnancy; the hernial sac had filled the whole of the left part of the thorax and contained half the ventricle, the whole of the small intestine and the major portion of the large intestine, as well as the pancreas.

The author used the abdominal approach in operating on 5 of the patients, 2 of whom died; the thoracic route was used in 1 case this patient died 2 patients were not operated upon and 1 of these died from incarceration. All survivals are classed as bullet or splinter cases. The author is of the opinion from a technical point of view that a laparotomy can be less difficult than one might imagine. The diagnosis of diaphragmatic hernia is not an easy task and confirmation by x-ray examination with contrast media is imperative. When the diagnosis has been ascertained and the health permits, operation should be performed preferably during an interval devoid of symptoms. PAUL MANNING, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Glenn, F.: The Surgical Treatment of 1,545 Hernias. *Ann. Surg.* 1947 135 72.

Fifteen hundred and forty five hernias treated surgically over a five year period (1940-1944) are reported.

The majority of the postoperative complications are systemic and are of vascular or pulmonary origin. Local complications for the most part are due to infection.

Fifty per cent of the deaths, and many of the complications, occurred in patients who presented themselves for operation with acute hernia. This term has been employed to designate those patients who require immediate operation because of incarceration or strangulation of the bowel. An incarcerated hernia may not necessarily be an emergency but immediate operation to exclude the possibility of strangulation is often indicated because the transition from incarceration to strangulation and intestinal obstruction occurs too frequently to be disregarded.

Recent literature reveals that at the present time silk is employed most frequently in the repair of hernia. Cotton suture material is becoming more popular and the use of steel wire, as advocated by Babcock, is increasing.

As other reports on the experience of early mobilization of patients have appeared, it is evident that the trend to get patients (who have had repair of direct inguinal hernia of the congenital type) out of bed on the day following operation, is justified. However until longer follow up studies are available definite conclusions cannot be stated. The mobilization of the structures in the repair of any hernia and their meticulous approximation without tension, by suture material that produces the least reaction, as insisted upon by Halsted in 1893, remains the important principle in this field of surgery.

JOHN J. MALONEY, M.D.

Bhajejar, M. V.: Strangulated Inguinal Hernia: Observations in 89 Cases. *Arch. Surg.* 1947 54 41.

The author attempts to describe the morbid anatomic evolution of a strangulated hernia based on his experience with 50 cases seen in Bombay India.

The anatomic changes that are brought about as a result of the constriction which gradually leads to strangulation affect the mesentery, the blood vessels in the mesentery and in the bowel wall, and the wall of the intestine itself.

Twelve cases are illustrated to depict, in chronological order, the seven stages in the evolution of a strangulated hernia, from the stage of mere congestion to one in which the intestinal loop becomes nonviable, the pathologic appearances in the formation of a hematoma, from the stage of dilatation of the veins in the mesentery to the stage when a hematoma

may occupy a large portion of the mesentery and the relation between the changes that take place in the mesentery and the bowel wall.

One may therefore conclude that the seven stages in the evolution of a strangulated hernia are: the stage of congestion, the stage of cyanosis with edema of the mesentery and visible dilated veins, the stage of appearance of hemorrhagic spots, the stage of cyanosis with hemorrhagic spots, the stage of cyanosis of the bowel wall with a hematoma in the mesentery, the stage of deeper cyanosis with blue black bands in the wall of the intestine or a rough wet, blotting paper appearance with a large or peripheral hematoma in the mesentery and the stage of nonviable loop.

In every case the bowel wall that appears affected always corresponds to the portion of the mesentery which is also affected. The margin of the hematoma and the line of demarcation of the affected and normal parts of the loop always stop short sharply at the line of constriction.

Clinically as a guide to the surgeon who is operating on patients with strangulated inguinal hernia, the cases can be divided into three groups, as follows:

One group consists of cases in which, on opening the sac, only the color of the bowel wall is found to be slightly altered, the bowel being normal in every other way and peristalsis present as in the normal intestine. In such cases the intestinal loops may be immediately and safely returned into the abdominal cavity.

A second group consists of cases in which there are changes in the bowel wall and/or in the mesentery—changes affecting the color and condition of the bowel wall in varying degree and changes in the mesentery from its mere thickening to a large hematoma. When the changes are slight, the normal color returns within a short time after relief of the constriction and the application of packs of warm isotonic solution of sodium chloride. In more advanced cases it may take several minutes before any appreciable change in the color may be detected. Also it may take some time for the peristalsis to reappear, but once the peristalsis has definitely begun, no matter what the color, feel or odor of the bowel wall and/or of the mesentery may be, so long as reintroduced peristalsis persists and there is no perforation, the loop may confidently be returned to the abdominal cavity. The presence or absence of peristalsis is the only sure token of the viability or nonviability of the bowel wall and is the only sure criterion as to whether the intestines should be returned into the peritoneal cavity.

In the third group are included the cases of strangulation in which the loop does not regain its peristaltic power and must therefore be considered as nonviable, even if the color and other changes are not those typical of a nonviable loop. In such cases appropriate surgical procedures must be carried out.

All 50 of the patients were males, and all were operated on under spinal anesthesia.

The hernias were of the indirect inguinal type and the majority were on the right side. There were no cases of bilateral strangulation.

In the majority of the cases (36 or 72 per cent) the sac contained loops of small intestine.

Of the 50 patients, 5 (10 per cent) died before their discharge from the hospital.

A brief description of the operation is included.

HARRY W. FINE, M.D.

Blintcliffe, E. W.: Mesenteric Vascular Occlusion. *Brit. M. J.*, 1947 1: 50.

Occlusion of the mesenteric vessels is not common; the diagnosis is difficult, and the mortality rate is high. Believing that with wider recognition and earlier treatment the gloomy prognosis would be improved, the author discusses the anatomy, pathology, and etiology of the condition and considers the diagnosis and treatment.

The occlusion primarily may be arterial or venous, the latter being more common, but with development of the condition both arteries and veins are involved. Arterial occlusion is usually due to an embolus derived from mitral stenosis, mural endocarditis, atheroma, pulmonary vein thrombosis, or pyemia. The superior mesenteric artery is more often involved than the inferior.

The cause of venous thrombosis frequently cannot be demonstrated; portal pyemia or thrombosis secondary to appendicitis, diverticulitis or pelvic infection is an important factor as all of the mesenteric venous circulation passes through the liver. Portal obstruction due to cirrhosis, peripheral venous thrombosis and changes in the blood *per se* such as polycythemia rubra, leucemia, or anemia may be the initial lesion.

The diagnosis of mesenteric vascular obstruction is difficult; the symptoms are essentially those of intestinal obstruction and peritoneal irritation. In cases of massive occlusion the element of obstruction may be overshadowed by signs of internal hemorrhage due to the large amount of blood which may be lost from the infarcted intestine. Some of this blood may become evident as hematemesis or melena. Sallient points to note in attempting a diagnosis are: (1) history or signs of a possible causative lesion—for example, endocarditis or cirrhosis; (2) melena or the revelation of blood on rectal digital examination or on enema; (3) the presence or previous history of vascular occlusion elsewhere; (4) the presence of a blood dyscrasia; and (5) severe pain, often greater on the left side, associated with signs of intestinal obstruction, free abdominal fluid, and sometimes a palpable mass. A differential diagnosis from other types of intestinal obstruction, perforated peptic ulcer and acute pancreatitis must be made.

Exploratory laparotomy must be undertaken early; 95 per cent of patients who are untreated will die, and the time factor is as important as in perforated ulcer. Wide resection of the bowel and

mesentery extending into healthy tissue, is required, and the presence of a second infarct involving another loop of bowel must not be overlooked. While the author recommends primary anastomosis of the small bowel segments, he believes that external drainage should be carried out in cases in which the colon is involved, with the continuity being re-established at a later date.

Two cases of mesenteric venous thrombosis with complete recovery are presented. The possibilities of the use of heparin as an adjunct to surgery is suggested.

WAYNE CAMERON, M.D.

Altmeier, W. A. and Holzer, C. E.: Primary Torsion of the Omentum. *Surgery* 1946, 20: 810.

Obesity and strenuous physical activity are probably important predisposing factors of omental torsion, although the true cause is probably still unknown.

The location of the mass in the right portion of the omentum, usually just above the level of the incision, supports the opinion of Morris that the right half of the omentum is longer and more subject to torsion.

Idiopathic torsion of the omentum is a rare condition, only 64 previous cases having been reported in the literature. Its cause is obscure, but adiposity and strenuous physical activity apparently are predisposing factors.

The condition is usually confused with acute appendicitis, but should be suspected in an obese or robust patient complaining of pain of several days duration in the right lower quadrant of the abdomen, beginning during strenuous physical activity and being unassociated with vomiting.

The treatment of choice is excision of the gangrenous portion of the omentum with ligation of the vessels of its pedicle. The prognosis is excellent.

Primary torsion of the omentum should be looked for when laparotomy for acute appendicitis reveals a normal appendix and no other explanation of the clinical signs and symptoms, particularly the presence of sanguineous intraperitoneal fluid. A careful search is necessary to demonstrate the lesion which is usually located in the right paracolic gutter or lower portion of the right upper quadrant of the abdomen.

JOSEPH GARTER, M.D.

GASTROINTESTINAL TRACT

Brummer, P.: On the Mucin Content of Gastric Juices. *Acta med. scand.*, 1946, 20: 324.

Five methods of mucin determination and their shortcomings are briefly discussed. The methods are based on (1) surface tension or viscosity; (2) measurement of the sediment after spontaneous centrifuging; (3) estimation of the nitrogen content of the gastric juice; (4) the reductive power of mucin measured either directly or after acid hydrolysis; and (5) the estimation of the turbidity produced by trichloroacetic or salicylaldehyde acid precipitate.

The author sought first to separate mucin from the proteins in the gastric contents. Picric acid precipi-

tated the proteins completely leaving the mucin totally unprecipitated. The mucin was then precipitated from the filtrate with alcohol. The author gives in detail the specific steps in his procedure.

Studies were made of 313 specimens of gastric juice from 145 persons, 50 of whom were healthy and 95 of whom suffered from various gastric disorders. The mucin content of the gastric juice varied from 0.15 to 1.5 per cent, the average being about 0.5 per cent. No definite relation between the macroscopic mucin and the mucin content was found to exist as the colloidal state of mucin depends upon the acidity of the gastric juice. Therefore, mucin appears to be absent or of small quantity when acidity is high.

After test meals the mucin content was slightly higher than when the individual had an empty stomach. Histamine and insulin appeared to have no effect on the mucin content. Vagotomy has been reported as increasing the mucin content but the few cases checked by the author did not support this finding.

The mucin content in cases of peptic ulcer and gastritis was within normal limits. This is contrary to the previous conception that a lowered mucus content exists in peptic ulcer and is of importance in its pathogenesis. No other clear evidence could be found of any difference between the mucus content of the gastric juice of healthy individuals and that of individuals suffering from various gastric disorders.

FREDERICK C. HORNEL, M.D.

Esfakind, L.: The Problem of Hypoproteinemia in Delayed Gastric Emptying after Stomach Resection. *Acta chir scand.*, 1947, 95, 81.

The author takes issue with the commonly accepted thesis that postoperative hypoproteinemia is a direct cause of retention in gastrointestinal anastomoses. It is commonly accepted that the underlying cause of defective passage in such cases is due to edema of the anastomotic line.

The present study is based on the analysis of 315 patients who underwent a Moynihan type of gastric resection. The material is analyzed on the basis of the patients who had retention complications and in whom serum protein studies were made both with and without protein therapy. Evidence of external edema was correlated.

Most of the patients with retention who showed signs of protein alterations were subjected to an intense parenteral administration of protein in the form of serum or blood. The effect was very variable. Only in a very few cases was there improvement of passage after protein restitution within a short enough period of time to be significant. However such treatment had a very positive effect on external evidences of hypoproteinemia, such as ankle edema.

It is concluded that in acute hypoproteinemia following gastric resection the edema about the anastomotic line is not demonstrably related to postoperative passage delay in chronic hypoproteinemia with anemia, the concomitant occurrence of these conditions with carcinoma is so frequent that a causal rela-

tionship between hypoproteinemia and edema about the anastomosis cannot be made with certainty. Furthermore, patients with external evidence of hypoproteinemic edema do not have a higher retention frequency than those without edema. Thus, it would seem that visceral edema plays a negligible role in delay of postoperative passage and explains the author's poor results with protein therapy for this postoperative complication. Protein therapy had a good effect on hypoproteinemic ankle edema but did not relieve obstructive symptoms related to possible edema of the anastomosis.

HAROLD LAUFMAN, M.D.

Zettergren, L.: On Pyloric Hypertrophy in Adults. *Uppsala l  t f  ren f  rk.*, 1946, 52, 83.

The author gives a report of 12 cases pathologically diagnosed as hypertrophy of the pylorus in adults. The patients of whom 4 were women displayed protracted trouble of the gastroduodenitis type some with signs of pyloric stenosis. In 10 cases in which carcinoma of the stomach was found resection was performed. The sections revealed pronounced muscular hypertrophy chiefly of the inner coat of the tunica muscularis in the antral portion of the ventricle. The condition was analogous to infantile pyloric hypertrophy. The hypertrophy reached its maximum at the pylorus and diminished in degree toward the oral part of the antrum. In most cases there were signs of chronic gastritis which, in the author's opinion, can play a certain role etiologically. There occurred neither ulcer nor cicatricial ulcer in the mentioned parts of the ventricle in any of the cases. The author considers that there is no connection with the infantile pyloric hypertrophy, but, similarly spastic conditions are sometimes found to occur in the thickened musculature.

The possibility of making a clinically correct diagnosis is discussed. Therapeutically internal treatment with diet and antispasmodics should have a good effect on the spasm in itself while the performance of gastroenteroanastomosis should be a more adequate way of dealing with an organic muscularly conditioned pyloric stenosis provided there is no hyperacidity. The skill of the surgeon in estimating the nature of the pyloric thickening (hypertrophy, ulcer or cancer) at the operation is the decisive factor in the choice between the last mentioned surgical method and resection.

JOHN J. MALONEY, M.D.

Berg, B. N.: Gastric Ulcers Produced Experimentally by Vascular Ligation. *Arch. Surg.*, 1947, 54, 58.

Virchow's hypothesis that human gastric ulcers were vascular in origin led to several attempts to reproduce similar lesions in animals by ligation of the gastric vessels. For the most part no significant results were obtained.

In human beings the anatomic arrangement of the blood supply of the stomach is practically the same as that in dogs.

The rat's stomach is divided by a transverse ridge into two parts, a nonsecretory rumen or forestomach

I have been very busy with my work and have not had time to write to you. I am sorry about that. I am still in the hospital and am not feeling well. I am hoping to be home soon. I will write to you again when I am better.

[illegible][illegible]

It is the Author's intention to perform additional longitudinal

[illegible][illegible][illegible]

1. The first part of the report discusses the current state of the world economy and the impact of the global financial crisis. It notes that the crisis has led to a significant decline in global economic activity, with many countries experiencing recession. The report also highlights the challenges faced by developing countries, particularly in terms of access to credit and foreign investment.

2. The second part of the report focuses on the impact of the crisis on the environment. It notes that the crisis has led to a reduction in greenhouse gas emissions, which is a positive development. However, it also points out that the crisis has led to a reduction in investment in renewable energy and other sustainable technologies, which could have long-term negative impacts on the environment.

3. The third part of the report discusses the impact of the crisis on social issues, particularly in terms of unemployment and poverty. It notes that the crisis has led to a significant increase in unemployment, particularly in developed countries. This has led to a rise in poverty and social inequality, which are major concerns for many governments and international organizations.

4. The fourth part of the report discusses the impact of the crisis on the global financial system. It notes that the crisis has led to a loss of confidence in the global financial system, which has led to a decline in international trade and investment. This has led to a significant reduction in global economic activity, which is a major concern for many governments and international organizations.

5. The fifth part of the report discusses the impact of the crisis on the global political system. It notes that the crisis has led to a decline in international cooperation and a rise in protectionism. This has led to a significant reduction in global economic activity, which is a major concern for many governments and international organizations.

6. The sixth part of the report discusses the impact of the crisis on the global health system. It notes that the crisis has led to a decline in investment in health care and a rise in the number of people living in poverty. This has led to a significant increase in the number of people who are vulnerable to disease and other health problems, which is a major concern for many governments and international organizations.

7. The seventh part of the report discusses the impact of the crisis on the global education system. It notes that the crisis has led to a decline in investment in education and a rise in the number of people who are unable to afford education. This has led to a significant increase in the number of people who are illiterate and unable to participate in the global economy, which is a major concern for many governments and international organizations.

8. The eighth part of the report discusses the impact of the crisis on the global culture system. It notes that the crisis has led to a decline in investment in culture and a rise in the number of people who are unable to afford cultural activities. This has led to a significant increase in the number of people who are unable to participate in the global culture, which is a major concern for many governments and international organizations.

9. The ninth part of the report discusses the impact of the crisis on the global environment. It notes that the crisis has led to a decline in investment in environmental protection and a rise in the number of people who are unable to afford environmental protection. This has led to a significant increase in the number of people who are unable to participate in the global environment, which is a major concern for many governments and international organizations.

10. The tenth part of the report discusses the impact of the crisis on the global future. It notes that the crisis has led to a decline in investment in the future and a rise in the number of people who are unable to afford the future. This has led to a significant increase in the number of people who are unable to participate in the global future, which is a major concern for many governments and international organizations.

I am very glad to hear from you
 and hope you are well.
 I am well at present.
 Love,
 M. J.

11. J. M. Carlsson, K. S. and Smith R. C.:
The Effect of Testosterone on the
Clinical Course of the Prostate Gland.
J. Clin. Endocrinol. 1961, 21: 111.

[illegible][illegible]

The plasma level for the phenylmercaptide has not yet appeared.

In general, the total volume of gastric secretion was markedly reduced by vagotomy as well as the free hydrochloric acid content of the fasting stomach. While most of the patients showed a decrease or absence of free hydrochloric acid after vagotomy yet in 4 patients it had no demonstrable effect on the free hydrochloric acid levels.

One of the most striking results of vagotomy is the immediate, complete, and apparently permanent relief of pain. It would seem that there are 4 possible explanations for this phenomenon (1) the effect of anesthesia (ethylene ether) (2) interruption of the sensory pathways (3) decrease or absence of free hydrochloric acid and (4) decrease or absence of the peristaltic activity of the stomach. The effect of the anesthesia is transient and it would seem that the pain would certainly recur. It is difficult to prove that the pain pathways have not been interrupted. However, it is generally believed that visceral pain is carried by the splanchnic nerves. Furthermore, distention, traction and probably heat and cold are perceived by the patient after vagotomy. It is improbable that the relief of pain is due only to the decrease or absence of hydrochloric acid because in 4 patients who had normal free hydrochloric acid levels after vagotomy the pain was immediately relieved and did not recur. Also the introduction of free hydrochloric acid immediately after vagotomy and on several occasions later in 2 patients in this series and in 2 others not included in this report caused no pain, whereas, each patient had experienced typical pain after this procedure before operation.

Dilatation and delayed emptying of the stomach were a constant finding after vagotomy except in those patients who had a previous gastroenterostomy or gastric resection. The most striking effect of vagotomy in this series of patients was the reduction or absence of gastric motility so much so that one wonders if this is not the most likely explanation for the immediate relief of pain and subsequent healing of the ulcer.

CHARLES BARON M.D.

Brown, C. H., Colvert, J. R., and Brush, B. E.: Gas-troileostomy: A Rare Surgical Error; Symptoms and X-ray Findings. *Gastroenterology* 1947 8: 71

The common complications of gastrojejunostomy are well known, namely gastrojejunitis, gastrojejunal ulcer, nonfunctioning gastrojejunostomy stoma, perforation of a marginal ulcer, and gastrojejunal fistula. Rarer but none the less typical is the syndrome which occurs in patients in whom a gastroileostomy was done by mistake.

The authors briefly review the literature and find only 22 cases of gastroileostomy which have been reported. Because of the obvious importance of this surgical error and the necessity of promptly recognizing its signs and symptoms the authors present 3 additional cases of gastroileostomy and analyze the syndrome.

The predominant symptoms are loss of weight, pain, vomiting, which may be fecal in type, and diarrhea. In 1 of the present cases reported it is sig-

nificant to note that the patient actually tasted soap following a soap-suds enema on the fifth postoperative day. The stools may contain undigested food material. Whether diarrhea or vomiting predominates apparently depends upon the patency of the pylorus and the operative stoma when the stomach is filled. Malnutrition and weight loss may be marked due to interference with normal digestion and assimilation. Pain is a common symptom and may be severe. Hemorrhage was present in 3 of the 22 cases. Ileac ulcer was not as common as might be expected from the fact that unneutralized acid gastric chyme came in direct contact with the mucous membrane of the ileum.

X-ray examination including particularly serial barium meal films of the gastrointestinal tract is most helpful in diagnosis. Two of the 3 cases reported showed refilling of the stomach some hours after it had emptied an x-ray sign not previously emphasized. This is probably the result of the fact that the barium passes through the patent pylorus into the duodenum through the jejunum and then through the gastroileal stoma back into the stomach.

In the authors' series of 3 cases simple disconnection of the gastroileostomy promptly produced satisfactory results. However in 1 of the patients a partial gastrectomy was also performed.

EDWARD F. LEWIS, M.D.

VanLiere, E. J., Stickney, J. G., and Northrup, D. W.: Comparative Study of the Effect of Anesthetic Agents on the Propulsive Motility of the Small Intestine. *Gastroenterology* 1947 8: 82

In studying the problem of propulsive motility of the small intestine as affected by various anesthetic agents the authors are underscoring and trying to shed additional light upon the well recognized fact that disturbances of intestinal motility play a very important role in the incidence of morbidity and mortality in the postoperative period. It is, however, unfortunate that postoperative ileus and related disorders cannot be explained on the basis of a single etiological factor. The type and duration of the operation as well as the care and gentleness with which the intestines are handled are all important factors among many others, in the problem of postoperative complications. Nevertheless any experimental evidence which seeks to provide additional information on the incidence and cause of such disturbances following abdominal surgery is of value even if the results are somewhat confusing and the interpretation subject to cautious consideration.

The effects of cyclopropane, chloroform, ether, ethylene nitrous oxide, and a number of barbiturates on the propulsive motility of the small intestine were studied experimentally in 128 dogs.

In group A a charcoal mixture was given by stomach tube to normal dogs. At the end of 30 minutes they were sacrificed and the distance the mixture had been propelled by peristaltic action was measured. In group B the dogs were first anesthetized and the charcoal mixture put directly into the

10 Clinical course. This is essentially the same as that of a bulbar ulcer. Medical therapy was efficacious in 10 of the authors 16 cases being associated with both clinical and roentgenological improvement, although in some cases there was a persistence of duodenal irritability and cicatrization.

EUGENE J. ADRI, M D

Kittle C. F., Jenkins, H. P. and Dragstedt L. R.: Patent Omphalomesenteric Duct and Its Relation to the Diverticulum of Meckel. *Arch Surg* 1947 54 10.

A presentation of the history embryology anatomy pathology relation to other congenital anomalies, and sex incidence of the diverticulum of Meckel is given. The relationship between it and the patent omphalomesenteric duct is discussed.

One hundred and two cases of patent omphalomesenteric duct and 26 additional cases in which prolapse of the intestine occurred through this structure were collected from the literature. These are briefly summarized.

Two new cases of uncomplicated patent omphalomesenteric duct and 1 case with prolapse are presented.

The clinical features, diagnosis, and treatment of this condition are discussed.

Operation for excision of the patent omphalomesenteric duct should be undertaken as soon as the condition is diagnosed to avoid the hazard of intestinal prolapse.

JOHN J. MALONEY M D

Gardner R. H.: Volvulus of the Cecum. *Brit M J.*, 1947 1 83.

Volvulus of the sigmoid is a well known condition, while volvulus of the cecum is still believed to be rare. The author believes it is not so uncommon as supposed and cites 15 cases reported in 3 years, including 3 personal cases. He believes the condition should be more widely recognized since the mortality rate is very high if treatment is withheld. Partial torsion may occur in recurrent attacks over a period of years sometimes culminating in an acute complete torsion. It also may cause obscure abdominal pain or discomfort, or stimulate some cases of subacute appendicitis. Obstetricians should realize that this condition is likely to complicate pregnancy and the puerperium.

Wolfer (1942) reported 304 cases from the literature with mortality rates between 50 and 60 per cent in operative cases and rising up to 100 per cent in nonoperative cases. It should be possible to bring this high mortality rate down with early diagnosis and treatment.

In the third stage of the embryological rotation of the gut, the cecum lies beneath the liver and descends to the right iliac fossa finally becoming fixed to the posterior abdominal wall, and its mesentery disappears. If this fixation and disappearance of the mesentery fails to take place, the cecum and ascending colon are variably mobile in accordance with the length of this mesentery. Sometimes there is even a

common ileocecalocolic mesentery. This renders the cecum and a varying amount of the right half of the colon liable to torsion. Points of fixation at the base of this mesentery—at the hepatic flexure or where the transverse colon crosses the duodenum—frequently act as hubs around which the torsion occurs.

The frequency of this nonfixation of the cecum and right colon is given at from 15 to 25 per cent. Any of the cases in this group may develop a volvulus. Rarer causes are errors of rotation (nonrotation, reversed rotation, and nondescent of the cecum). The twist more commonly occurs in a clockwise direction.

Males are afflicted more often than females in a 3 to 1 ratio and one-half of the patients are between the ages of 20 and 40. Exertion or heavy occupations may account for the male preponderance. Trauma sudden or gradual changes in position of the viscera, (as seen in pregnancy or the puerperium) mesocolic inflammation dietetic errors gaseous distention or violent purgation may be exciting causes.

The author divides the cases into 3 types according to their rate of onset and manifestation of symptoms.

1 Acute cases come on within a few hours and cause violent abdominal pain, vomiting and constipation followed by abdominal distention—signs of acute obstruction. These cases are rapidly fatal and must be subjected to operation in good time.

2 The subacute cases give a history of several hours up to more often, 3 or 4 days of variable abdominal discomfort or distention, pain and tenderness. The pain may be epigastric or in the right lower quadrant. The temperature and pulse often remain normal. The patient will nearly always recall similar attacks of a milder nature which have passed off without incident (indicating a volvulus that has righted itself). Tenderness is usually present and is localized over the distended gut and the area of peritonitis developing over and around it. Distention is usually gross and roentgenograms of the abdomen will frequently be diagnostic.

3 The chronic cases show a transient partial volvulus which sooner or later untwists. These cases are associated with right lower quadrant pain, tenderness and varying degrees of distention. Histories of distention suddenly relieved by the passage of a large amount of flatus are often of great importance in the diagnosis.

This condition has been reported as an acute complication of pregnancy or the puerperium. Rose believes that volvulus may be the cause of distention early in the puerperium and that laparotomy should be seriously considered if it refuses to respond to treatment in 24 hours post partum.

The treatment of volvulus consists of early laparotomy and care of the gut according to the state in which it is found. If it is viable derotation with or without fixation or derotation with a cecostomy to decompress and drain the bowel is indicated. If it is gangrenous, exteriorization and removal with the cautery and subsequent closure of the enterostomy or resection (right hemicolectomy) and anastomosis of the ileum to the transverse colon is indicated.

Adequate preoperative treatment as far as time will allow is important. Blood and fluid should be replaced. Gastric suction and lavage are of value before and after operation.

Fixation of the viable bowel may be achieved by Waugh's method, by fixing the appendectomy stump to the anterior abdominal wall with a pursestring suture or by cecostomy fixation. Very careful handling of the distended friable gut is essential.

The author's 3 cases are presented in detail.

ROBERT R. BICKLOW M.D.

Mirvish L.: Diverticulitis of the Cecum. *Clin Proc Cape Town*, 1946, 5: 354.

This is a case report of a patient with multiple diverticulitis of the colon. The interesting phase of this report is that there were several diverticula of the acquired type in the cecum. Solitary diverticula of the cecum are encountered not infrequently; they are usually congenital in type. Most cases of cecal diverticulitis are diagnosed as acute appendicitis when one of the cecal diverticula becomes inflamed.

In this case the clinical picture did not appear to resemble acute appendicitis with abscess formation but seemed more like carcinoma of the cecum. The diagnosis was confirmed by roentgenography and the patient recovered without surgery.

HAROLD LAUTMAN M.D.

Koch F.: A Contribution to the Operative Treatment of Cancer of the Rectum. *Acta chir scand* 1947, 93: 145.

In the Surgical Clinic of Malmö in Sweden the favored procedure in the treatment of carcinoma of the rectum during the last 30 years has been to operate in one stage and preserve the anal sphincter whenever possible. The reported material consists of 276 cases of rectal cancer.

The majority (56 per cent) of patients in this series did not seek medical aid until symptoms had persisted 6 months or more. Twenty-one per cent of the patients sought medical aid earlier but the nature of the lesion was not diagnosed. The author found that radical operability in delayed cases was reduced to 17 per cent while in all other cases the operability was 36 per cent. These figures are considerably lower than in most large series reported in recent years.

The choice of method for radical operation is largely governed by two considerations: whether the sphincter can be spared and whether the operation can be performed in one stage. It is the author's contention that, whenever possible, the sphincter should be preserved and every attempt is made to complete the operative procedure in one stage. In the present series there were 87 radical operations, of which 66 were resections with preservation of the sphincter. There was only a 7.5 per cent incidence of postoperative urinary retention in the series. All of the patients in these cases recovered after a few days of catheterization with no serious complications of the genitourinary tract. The author attributes this ex-

cellent record to great care in avoiding damage to the blood supply of the bladder.

The immediate mortality was 21 per cent. In 8 cases the cause of death was peritonitis originating from the wound. In 6 it was failure of the circulatory apparatus. In another 6 the patients died in the hospital 1 month or more after surgery from various complications such as pneumonia and thromboembolic phenomena. If the latter 6 cases are included, the hospital mortality was 30 per cent. Apparently all patients in whom the sphincters were preserved had good control upon discharge from the hospital.

Follow-up examination revealed that there was a 64 per cent incidence of 3 year cures and a 30 per cent incidence of 5 year cures. None of the patients who were re-examined complained of defective control of the anal sphincter. On the basis of the material in this report, the author believes that preservation of the sphincter does not appreciably alter the result as compared with those of other radical resections and therefore recommends this procedure whenever feasible. He claims that disturbances in sphincter control and the presence of persistent fecal fistulas have been overestimated in the literature, especially since neither of these complications occurred in any of his cases.

HAROLD LAUTMAN M.D.

Swinton N.W.: Pruritus Ani. *England J M* 1947, 236: 169.

The etiology of anal pruritus is not definitely known and there may be several etiologic factors involved in many of the cases. Some precipitating factor begins anal pruritus. It often follows a period of diarrhea, constipation, fatigue, worry or nervous tension. The symptoms may be transient or may set up a cycle of scratching and itching that is progressive. It is of value in all cases for the doctor to spend time with the patient talking over the possible causes and explaining the mechanism of the scratch-itch cycle and the importance of avoiding scratching.

The anorectal area contains a sweat apparatus, the apocrine system which is part of the sexual glandular system. Its excretion is alkaline and contains protein and excess carbohydrate. It is responsive to emotion and sexual tension.

Fungus infections have been found to be present in as high as 60 per cent of the cases of anal pruritus by some writers, but the author's study did not support these findings. Various bacterial organisms, probably of little importance, have been described.

Food allergies have occasionally been found, but it is difficult to evaluate them. Excess carbohydrate in the diet increases the alkalinity around the anus and increases the local hydration. Fruit juices have a similar effect and alcohol may be important as a peripheral dilator.

The sodium salts of fatty acids in soap, the sulfite in some toilet papers, the phenolphthalein in laxatives, and the mercury in some surgical lubricants may increase the local irritation.

The psychogenic factor is important, and nearly all patients with an intractable itch give histories of

episodes causing tension. There is an anal erotic type of anal pruritus. Sexual problems enter into many cases.

Anal abrasions, fissures, fistulas, hemorrhoids, skin tags, a contracted anal ring, or infected crypts may be precipitating factors.

Therapy of these cases must stress treatment of the entire patient as contrasted with the usual tendency toward intense local therapy. Rest, relaxation, and relief from tension must be attained by sedation and hospitalization if necessary. Alcohol, carbohydrates and roughage are reduced in the diet. Cleanliness is stressed; cotton and water should be used to cleanse the area, and toilet paper, soap, and direct manual contact with the anus should be avoided. Potassium permanganate (65 mgm. to 1 liter) in hot water is used in mild cases and patients are advised to sit in it as often as necessary. Burrow's solution and dilute Castellani carbolfuchsin paint, with or without resorcinol, are helpful. Ointments are avoided.

There are definite indications for surgery in these cases, but they are few and are becoming less with the greater experience in the handling of such cases. Alcohol and other injections have the common denominator of producing local anesthesia and should be reserved for severe cases. When such treatment was indicated, the author had his best results following the Buie technique of alcohol injection.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Ivy A. G.: Motor Dysfunction of the Biliary Tract: An Analytical and Critical Consideration. Caldwell Lecture, 1946. *Am. J. Roentg.*, 1947, 57.

Does biliary dyskinesia exist as a clinical entity and how can it be diagnosed? This article is an analysis of the present state of the problem.

Anatomically the gall bladder has a fibromuscular layer but muscular fibers are sparse in the cystic, hepatic, and common bile ducts. Embryologic evidence shows that the sphincter of Oddi develops independently of the duodenal musculature. There are four intrinsic muscles in the sphincter and ampulla of the adult. There are two longitudinal bundles which shorten the duct and erect the papilla. There is an annular sheath around the common duct from the point where it enters the duodenal wall to where it joins the pancreatic duct. There is an annular sheath around the terminal end of the pancreatic duct in about one third of the adults and around the ampulla in about one-sixth of the adults. Hypertrophy of the sphincter of Oddi has been reported and is said to occur after cholecystectomy.

Physiologically the gall bladder evacuates under the force of its contraction which is initiated by cholecystokinin, a hormone elaborated by upper intestinal mucosa when in contact with fat or partially digested protein. When injected intravenously

cholecystokinin will evacuate the gall bladder in dogs and man. In dogs the maximum force of the contracting gall bladder amounts to from 20 to 25 cm. of water pressure which is lower than the secretory pressure of bile and pancreatic juice which ranges from 25 to 30 cm. of water pressure.

In all animals that have a gall bladder we may believe, the common duct possesses a sphincter mechanism which is intimately co-ordinated with duodenal tone and motility but which may also act independently.

The sphincteric mechanism can exert a resistance to the flow of fluid amounting to from 60 cm. to 80 cm. of water pressure in the dog and therefore presumably it is possible for a spastic sphincter to resist a flow greater than the capacity of the gall bladder to contract and greater than the secretory pressure of the liver. The normal resistance of the sphincter in the cholecystectomized human being ranges from 0 to 23 cm. of water pressure and usually ranges from 10 to 15 cm. of water pressure.

In the dog after a meal of injected cholecystokinin, the gall bladder contracts and the sphincter of Oddi relaxes. In man the sphincter is known to relax in the presence of a fatty meal. This demonstrates a probable reciprocal innervation which if disturbed could cause pressure in the biliary tract and produce symptoms.

The source of pain in the biliary passages has been investigated but in human beings the evidence is meager principally because experiments were made in the presence of inflamed bile passages in which the pain threshold was lowered. In dogs 27 cm. of water pressure which is approximately equivalent to the maximum contraction of the gall bladder and secretory pressure of bile produced pain. All experiments through T tubes in human beings indicated that a sudden increase in intraductile pressure produced pain while a gradual increase did not and that the greater inflammation of the passages was accompanied by a lower pain threshold. Duodenal spasm as the cause of pain was ruled out in one series of experiments by the presence of an intraduodenal balloon.

Normal patients and patients operated upon some time previously have been investigated in three ways. First, with a duodenal tube in place olive oil was injected to cause contraction of the gall bladder. Pilocarpine causing sphincter spasm, was then injected this produced distress and the flow of bile ceased. Atropine was then injected and the distress disappeared as the bile reappeared. In the second experiment dehydrocholic acid which causes brisk bile formation, was injected intravenously into a patient with stenosis of the common duct and caused pain. This was confirmed on the dog. In the third experiment, secretin-cholecystokinin was injected intravenously in a patient following the introduction of a duodenal tube and obtaining bile. In 3 of the 19 patients the flow of bile ceased before the injection only clear pancreatic juice was obtained following the injection and the patient developed right hy-

pochoondrial distress. Magnesium sulfate in the duodenum relieved the distress and produced a copious bile flow.

Only manometric studies can make a diagnosis of motor dysfunction of the sphincter of Oddi at present. In the presence of a gall bladder delayed evacuation during a cholecystogram has been considered of diagnostic aid but evidence is contradictory and meager. The stimulus of a fatty meal is too variable for standardization of the procedure. Visualization of the hepatic ducts with a normal gall bladder *in situ* may occur with or without pain, generally the latter and is, therefore, neither helpful nor easy to explain.

The author suggests studying such patients with secretin-cholecystokinin as outlined in conjunction with cholecystography and attempts to visualize the hepatic ducts during cholecystography by feeding three egg yolks in milk. The latter could also be introduced into the duodenum directly and the patient given morphine hypodermically to contract the sphincter of Oddi in order to observe whether pain occurs during gall bladder contraction.

Postcholecystectomy colic in the absence of organic causes, or gross liver or bile duct disease must be considered as being due to sphincter spasm. In some cases if the colic is induced by $\frac{1}{4}$ gr. of morphine the diagnosis may be strongly suspected. A more radio-paque dye than now exists and which would be excreted by the liver in sufficient quantities to visualize the ducts without concentration should help in the diagnosis. FARMER C. HOSAK, M.D.

Varco R. L.: Intermittent External Biliary Drainage for Relief of Pruritus in Certain Chronic Disorders of the Liver. *Surgery* 1947 43

Pruritus caused by certain chronic disorders of either the hepatic parenchyma or the intrahepatic biliary system (chronic hepatitis or cirrhosis) causes unrelenting annoyance and is intractable to the therapy now customarily employed dihydroergotamine (intramuscular) procaine hydrochloride (intravenous) sedatives, hypnotics, and analgesics.

Varco reasoned that if it is true that the intractable pruritus is caused by the abnormal retention of bile salts then the development of a method for the reduction of the serum bile salt should constitute a rational therapeutic approach to this problem. As a result of the previous studies by Whipple and his collaborators it was believed that because 90 per cent of the total quantity of bile salts secreted each 24 hours is resorbed from the intestinal tract, recirculated through the liver and then re-eliminated in the bile, only pre-enteric deviation of the bile would reduce the serum bile salt level.

Upon translating these conjectures into surgical procedures it was determined that intermittent external biliary drainage suffices to attain and maintain prompt and virtually complete relief from the type of pruritus under consideration. The most effective operative procedure for this purpose is cholecystostomy and drainage of the common bile duct with a T-tube, size 10 to 12 French.

Small quantities of bile salts were given orally upon 3 occasions to patients who had an external biliary fistula. Pruritus promptly returned and then disappeared with the maintenance of intermittent external biliary drainage. ROMER TUCKER, M.D.

Mallet-Guy P., and Jeanjean R.: Surgical Eventualities in So-Called Medical Jaundice (Eventualités chirurgicales dans les ictères dits "médiacs") *Lyon chir.* 1946, 4: 1389.

The author discusses the possible surgical complications of infectious jaundice, particularly dyspeptic disturbances persisting after subsidence of infectious jaundice relapsing episodes of jaundice, and abnormal prolongation of jaundice.

If surgical exploration for one of these conditions fails to reveal a lesion in the biliary tract or the head of the pancreas, the symptoms are probably due to (1) hypertony of the sphincter of Oddi, (2) hypotony of the sphincter of Oddi, or (3) a variable degree of compression of the common bile duct usually associated with a chronic pancreatitis.

These may be differentiated from one another by manometric and roentgenographic studies of the biliary duct system made by cannulating the biliary tree at the time of operation. Usually the surgeon will find a precise disturbance of biliary function, either a relative degree of obstruction due to pancreatitis or a hypertonic or hypotonic sphincter of Oddi.

For obstruction due to pancreatitis, cholecystostomy is indicated. Biliary anastomosis is not indicated unless the obstruction is great enough to indicate some other condition than infectious jaundice. Similarly for cases of hypertonicity of the sphincter cholecystostomy appears to interrupt the evolution of sphincter spasm. However when the hypertonicity is too severe to be relieved by simple drainage, transduodenal sphincterotomy is preferable and restores a more normal tonicity of the sphincter. If on the other hand, a state of atony of the biliary tract and sphincter exists simple drainage of the gall bladder is the preferred treatment. In some of these cases splenectomy also is of value.

EDWARD W. GIBBS, M.D.

Clavel, C., and Dumas, J.: Acute Calculous Cholecystitis in Children (La cholecystite calculuse aiguë chez l'enfant) *Lyon chir.* 1946, 4: 1

Acute calculous cholecystitis is rare in infants and children. The authors collected 103 cases and found that the greatest incidence of lithiasis in children occurred prior to the age of 1 year and just before the age of 15 years. Calculous cholecystitis is rare before the fifth year of age. Before the age of 10 acute cholecystitis occurs more frequently in males, but after the age of 10 the incidence is greatest in females.

The classical list of predisposing causes of calculous cholecystitis in children includes typhoid fever scar latina, gripe, pneumonia, upper respiratory infection, gastrointestinal illness, intestinal parasites, appendicitis, and heredity. However in many cases

neither the antecedent history nor the operative findings suggested any definite predisposing cause.

There is nothing characteristic about the pathological findings in infants. Calculi of varying size number, and chemical composition are described. Examination of the gall bladder wall and lumen discloses the characteristic findings of acute cholecystitis, of catarrhal, suppurative or gangrenous type.

There is no doubt of the congenital origin of calculi for they have been described in the newborn and even in the fetus. In infants and children the pathogenesis appears to be the same as in adults except for the sudden increase in frequency of the disease in girls just before puberty which suggests an endocrine or vagosympathetic disturbance.

In a clinical study of 22 cases the authors found 8 cases of suppurative cholecystitis, 1 case of gangrenous cholecystitis, 10 cases of catarrhal cholecystitis, and 3 cases of cholecystitis with the complication of perforation or fistula formation.

Appendicitis is the most common diagnostic error. However in infants there are a certain number of gall bladder syndromes without lithiasis namely typhoid cholecystitis, scarlatina cholecystitis external compression of the biliary tract by adenopathy intestinal worms and acute noncalculous cholecystitis. Also lithiasis is seen without cholecystitis and in some cases of hemolytic icterus.

The diagnosis is based on symptoms of pain, constipation, high fever and leucocytosis with a predominance of polymorphonuclear cells added to the picture of noncomplicated lithiasis producing painful crises and hepatic colic. If this picture can be distinguished from other acute peritoneal syndromes by its localization and clinical history an accurate diagnosis can be made.

Congenital lithiasis often associated with malformations of the biliary passages, is frequently fatal. Acquired cholelithiasis, if recognized and treated surgically bears a good prognosis.

The authors recommend early operation. Although cholecystostomy might at first seem to be particularly indicated in infants and children, the frequently encountered advanced changes in the gall bladder wall will often necessitate removal of the gall bladder.

EDWARD W. GIBBS, M.D.

Muir J. B. G.: Surgical Hazards in the Treatment of Cholecystitis and Cholelithiasis. *Austral N Zealand J Surg* 1946, 16, 14.

The author reviews the surgical hazards and results of 431 operations on the biliary tract. The pathological condition, the type of operation performed, and the causes of death in each group are discussed.

Two hundred and seventy-five cholecystectomies were performed for chronic cholecystitis and cholelithiasis, with 6 deaths—one due to pulmonary embolism, 3 to hepatorenal syndromes and 2 to internal hemorrhage. Cholecystostomies were done in 3 cases, with no deaths.

When surgical treatment was carried out in the presence of acute inflammatory changes in the gall

bladder the mortality rose from 2.18 per cent to 18.4 per cent. In all, 103 cases were recorded in this group and the pathological findings at operation included acute cholecystitis with commencing gangrene, perforation and peritonitis, cholecystoduodenal fistula, pancreatitis communicating with liver hydatid and empyema of the gall bladder.

Cholecystectomy performed in patients with acute cholecystitis carried with it a mortality of 20.6 per cent whereas the mortality following cholecystostomy was 15 per cent, despite the fact that it was selected for the poor risk cases.

The question whether cholecystitis in the acute stage should be treated conservatively or with immediate operation is discussed at length. Muir believes that generalization is impossible and that each case of acute cholecystitis should be treated on its merits, the patient being under observation in the hospital. Consideration of the local pathological process should always be borne in mind. Apart from a small proportion of Welchii infections the organisms causing cholecystitis are usually *Bacillus coli* and streptococci of low virulence. In the early stages the inflammatory process is catarrhal in type, and limited to the mucous membrane and submucous tissue. Provided there is no obstruction the tendency in first attacks is to subside, leaving local adhesions on the peritoneal surface of the organ and a thicker gall bladder wall.

The theory is advanced that in a number of cases of acute cholecystitis, mechanical and circulatory effects rather than bacterial infection are responsible for the principal pathological changes. The veins draining the gall bladder are much more closely incorporated with the cystic duct than is the cystic artery and so lead to edema, congestion, and infarction.

The necessity for immediate operation on the tender palpable gall bladder is argued, is based on the fact that the tension in the gall bladder may become so great that the blood supply is compressed, resulting in gangrene, that there is seldom any clinical indication during an attack of acute cholecystitis that pus is present, and that perforation in a "watched case" is frequently the first indication that the attack is not subsiding.

These complications of nonresolving acute cholecystitis are arguments in favor of early surgical intervention. There is little doubt that in a younger type of patient, whose liver function has not been impaired by numerous attacks of cholangitis, cholecystectomy performed in the early catarrhal stage, when the normal surgical anatomy is not badly obscured by inflammatory exudate—that is during the first forty-eight hours—is not a very formidable technical undertaking and the risk is not great. It must be remembered, however that these patients are not always seen at that stage and have usually been sick at home for several days before admission to the hospital, so that the day of admission is by no means the first day of the attack. A careful history and assessment of the local pathological process as a
